Merge Analysis

Analyst:	Trishul Palekar
Agency/Co.:	HDR Inc.
Date performed:	3/20/2008 1:45:04 PM
Analysis time period:	AM
Freeway/Dir of Travel:	I-35 Southbound
Junction:	9 US 56 Entr
Jurisdiction:	KDOT
Analysis Year:	2010
Description:	NEPA Traffic Study

Freeway Data

Type of analysis	Merge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	520	vph

On Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-flow speed on ramp	35.0	mph
Volume on ramp	60	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent Ramp		vph
Position of adjacent Ramp		
Type of adjacent Ramp		
Distance to adjacent Ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway		Ramp		Adjacent Ramp	
Volume, V (vph)	520		60			vph
Peak-hour factor, PHF	0.90		0.90			
Peak 15-min volume, v15	144		17			v
Trucks and buses	9		17			%
Recreational vehicles	0		0			%
Terrain type:	Level		Rolling			
Grade		%		%		%
Length		mi		mi		mi
Trucks and buses PCE, ET	1.5*		2.5			
Recreational vehicle PCE, ER	1.2*		2.0			
Heavy vehicle adjustment, fHV	0.957		0.797			
Driver population factor, fP	1.00		1.00			
Flow rate, vp	604		84			pcph

Estimation of V12 Merge Areas

L_{EQ} = (Equation 25-2 or 25-3)

P_{FM} = 1.000 Using Equation 0

$v_{12} = v_F (P_{FM})$ = 604 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
v_{FO}	688	4800	No
v_3 or v_{av34}	0 pc/h	(Equation 25-4 or 25-5)	
Is v_3 or v_{av34} > 2700 pc/h?		No	
Is v_3 or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-8)	

Flow Entering Merge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	604	4400	No

!

Level of Service Determination (if not F)

Density, $D = 5.475 + 0.00734\, v_R + 0.0078\, v_{12} - 0.00627\, L_A$ = 5.8 pc/mi/ln

Level of service for ramp-freeway junction areas of influence A

Speed Estimation

Intermediate speed variable,	M_S = 0.273
Space mean speed in ramp influence area,	S_R = 62.4 mph
Space mean speed in outer lanes,	S_0 = N/A mph
Space mean speed for all vehicles,	S = 62.4 mph

Diverge Analysis

Analyst: Trishul Palekar
Agency/Co.: HDR Inc.
Date performed: 4/2/2008 2:16:37 PM
Analysis time period: AM
Freeway/Dir of Travel: I-35 Northbound
Junction: 5 US-56 Exit
Jurisdiction: KDOT
Analysis Year: 2010
Description: NEPA Traffic Study

Freeway Data

Type of analysis	Diverge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	2070	vph

Off Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-Flow speed on ramp	35.0	mph
Volume on ramp	240	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent ramp		vph
Position of adjacent ramp		
Type of adjacent ramp		
Distance to adjacent ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway		Ramp		Adjacent Ramp	
Volume, V (vph)	2070		240			vph
Peak-hour factor, PHF	0.90		0.90			
Peak 15-min volume, v15	575		67			v
Trucks and buses	10		8			%
Recreational vehicles	0		0			%
Terrain type:	Level		Rolling			
Grade	0.00	%	0.00	%		%
Length	0.00	mi	0.00	mi		mi
Trucks and buses PCE, ET	1.5*		2.5			
Recreational vehicle PCE, ER	1.2*		2.0			
Heavy vehicle adjustment, fHV	0.952		0.893			
Driver population factor, fP	1.00		1.00			
Flow rate, vp	2415		299			pcph

Estimation of V12 Diverge Areas

L_{EQ} = (Equation 25-8 or 25-9)

P_{FD} = 1.000 Using Equation 0

$v_{12} = v_R + (v_F - v_R) P_{FD}$ = 2415 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
$v_{Fi} = v_F$	2415	4800	No
$v_{FO} = v_F - v_R$	2116	4800	No
v_R	299	2000	No
v_{3} or v_{av34}	0 pc/h	(Equation 25-15 or 25-16)	
Is v_3 or v_{av34} > 2700 pc/h?		No	
Is v_3 or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-18)	

Flow Entering Diverge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	2415	4600	No

!

Level of Service Determination (if not F)

Density, $D_R = 4.252 + 0.0086\ v_{12} - 0.009\ L_D$ = 17.8 pc/mi/ln

Level of service for ramp-freeway junction areas of influence B

Speed Estimation

Intermediate speed variable,	D_S = 0.455	
Space mean speed in ramp influence area,	S_R = 57.3	mph
Space mean speed in outer lanes,	S_0 = N/A	mph
Space mean speed for all vehicles,	S = 57.3	mph

Description: NEPA Traffic Study

Freeway Data

Type of analysis	Merge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	3250	vph

On Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-flow speed on ramp	35.0	mph
Volume on ramp	130	vph
Length of first accel/decel lane	1000	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent Ramp		vph
Position of adjacent Ramp		
Type of adjacent Ramp		
Distance to adjacent Ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway		Ramp		Adjacent Ramp	
Volume, V (vph)	3250		130			vph
Peak-hour factor, PHF	0.90		0.90			
Peak 15-min volume, v15	903		36			v
Trucks and buses	10		2			%
Recreational vehicles	0		0			%
Terrain type:	Level		Rolling			
Grade		%		%		%
Length		mi		mi		mi
Trucks and buses PCE, ET	1.5*		2.5			
Recreational vehicle PCE, ER	1.2*		2.0			
Heavy vehicle adjustment, fHV	0.952		0.971			
Driver population factor, fP	1.00		1.00			
Flow rate, vp	3792		149			pcph

Estimation of V12 Merge Areas

L_{EQ} = (Equation 25-2 or 25-3)

P_{FM} = 1.000 Using Equation 0

$v_{12} = v_F (P_{FM})$ = 3792 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
v_{FO}	3941	4800	No
v_3 or v_{av34}	0 pc/h	(Equation 25-4 or 25-5)	
Is v_3 or v_{av34} > 2700 pc/h?		No	
Is v_3 or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-8)	

Flow Entering Merge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	3792	4400	No

!

Level of Service Determination (if not F)

Density, $D_R = 5.475 + 0.00734\ v_R + 0.0078\ v_{12} - 0.00627\ L_A$ = 29.9 pc/mi/ln

Level of service for ramp-freeway junction areas of influence D

Speed Estimation

Intermediate speed variable,	M_S = 0.452	
Space mean speed in ramp influence area,	S_R = 57.4	mph
Space mean speed in outer lanes,	S_0 = N/A	mph
Space mean speed for all vehicles,	S = 57.4	mph

Merge Analysis

Analyst: Tom Hiles
Agency/Co.: HDR Inc.
Date performed: 3/27/2008 10:03:18 AM
Analysis time period: AM
Freeway/Dir of Travel: I-35 Southbound
Junction: 11 Gardner Entr
Jurisdiction: KDOT
Analysis Year: 2015
Description: NEPA Traffic Study

Freeway Data

Type of analysis	Merge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	560	vph

On Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-flow speed on ramp	35.0	mph
Volume on ramp	60	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent Ramp		vph
Position of adjacent Ramp		
Type of adjacent Ramp		
Distance to adjacent Ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway	Ramp	Adjacent Ramp	
Volume, V (vph)	560	60		vph
Peak-hour factor, PHF	0.90	0.90		
Peak 15-min volume, v15	156	17		v
Trucks and buses	18	3		%
Recreational vehicles	0	0		%
Terrain type:	Level	Rolling		
Grade	%	%	%	
Length	mi	mi	mi	
Trucks and buses PCE, ET	1.5*	2.5		
Recreational vehicle PCE, ER	1.2*	2.0		
Heavy vehicle adjustment, fHV	0.917	0.957		
Driver population factor, fP	1.00	1.00		
Flow rate, vp	678	70		pcph

Estimation of V12 Merge Areas

L_{EQ} = (Equation 25-2 or 25-3)
P_{FM} = 1.000 Using Equation 0
$v_{12} = v_F (P_{FM})$ = 678 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
v_{FO}	748	4800	No
v_{3} or v_{av34}	0 pc/h	(Equation 25-4 or 25-5)	
Is v_{3} or v_{av34} > 2700 pc/h?		No	
Is v_{3} or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-8)	

Flow Entering Merge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	678	4400	No

!

Level of Service Determination (if not F)

Density, $D = 5.475 + 0.00734\ v_R + 0.0078\ v_{12} - 0.00627\ L_A$ = 6.3 pc/mi/ln
Level of service for ramp-freeway junction areas of influence A

Speed Estimation

Intermediate speed variable, M_S = 0.273
Space mean speed in ramp influence area, S_R = 62.3 mph
Space mean speed in outer lanes, S_0 = N/A mph
Space mean speed for all vehicles, S = 62.3 mph

Analysis time period: AM
Freeway/Dir of Travel: I-35 Southbound
Junction: 12 Sunflower Exit
Jurisdiction: KDOT
Analysis Year: 2015
Description: NEPA Traffic Study

Freeway Data

Type of analysis	Diverge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	620	vph

Off Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-Flow speed on ramp	35.0	mph
Volume on ramp	90	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent ramp		vph
Position of adjacent ramp		
Type of adjacent ramp		
Distance to adjacent ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway	Ramp	Adjacent Ramp	
Volume, V (vph)	620	90		vph
Peak-hour factor, PHF	0.90	0.90		
Peak 15-min volume, v15	172	25		v
Trucks and buses	18	2		%
Recreational vehicles	0	0		%
Terrain type:	Level	Rolling		
Grade	0.00 %	0.00 %	%	
Length	0.00 mi	0.00 mi	mi	
Trucks and buses PCE, ET	1.5*	2.5		
Recreational vehicle PCE, ER	1.2*	2.0		
Heavy vehicle adjustment, fHV	0.917	0.971		
Driver population factor, fP	1.00	1.00		
Flow rate, vp	751	103		pcph

Estimation of V12 Diverge Areas

L_{EQ} = (Equation 25-8 or 25-9)
P_{FD} = 1.000 Using Equation 0
$v_{12} = v_R + (v_F - v_R) P_{FD}$ = 751 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
$v_{Fi} = v_F$	751	4800	No
$v_{FO} = v_F - v_R$	648	4800	No
v_R	103	2000	No
v_{3} or v_{av34}	0 pc/h	(Equation 25-15 or 25-16)	
Is v_{3} or v_{av34} > 2700 pc/h?		No	
Is v_{3} or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-18)	

Flow Entering Diverge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	751	4600	No

!

Level of Service Determination (if not F)

Density, $D_R = 4.252 + 0.0086\ v_{12} - 0.009\ L_D$ = 3.5 pc/mi/ln
Level of service for ramp-freeway junction areas of influence A

Speed Estimation

Intermediate speed variable, D_S = 0.437
Space mean speed in ramp influence area, S_R = 57.8 mph
Space mean speed in outer lanes, S_0 = N/A mph
Space mean speed for all vehicles, S = 57.8 mph

Agency or Company:	HDR Inc.
Date Performed:	4/2/2008 2:16:37 PM
Analysis Time Period:	AM
Freeway/Direction:	I-35 Northbound
From/To:	Edgerton Road to Sunflower Road
Jurisdiction:	
Analysis Year:	2010
Description:	NEPA Traffic Study

_____Flow Inputs and Adjustments_____

Volume, V	1205	veh/h
Peak-hour factor, PHF	0.90	
Peak 15-min volume, v15	335	v
Trucks and buses	9	%
Recreational vehicles	0	%
Terrain type:	Level	
Grade	0.00	%
Segment length	0.00	mi
Trucks and buses PCE, ET	1.5	
Recreational vehicle PCE, ER	1.2	
Heavy vehicle adjustment, fHV	0.957	
Driver population factor, fp	1.00	
Flow rate, vp	700	pc/h/ln

_____Speed Inputs and Adjustments_____

Lane width	12.0	ft
Right-shoulder lateral clearance	6.0	ft
Interchange density	0.50	interchange/mi
Number of lanes, N	2	
Free-flow speed:	Measured	
FFS or BFFS	70.0	mi/h
Lane width adjustment, fLW	0.0	mi/h
Lateral clearance adjustment, fLC	0.0	mi/h
Interchange density adjustment, fID	0.0	mi/h
Number of lanes adjustment, fN	0.0	mi/h
Free-flow speed, FFS	70.0	mi/h
	Rural Freeway	

_____LOS and Performance Measures_____

Flow rate, vp	700	pc/h/ln
Free-flow speed, FFS	70.0	mi/h
Average passenger-car speed, S	70.0	mi/h
Number of lanes, N	2	
Density, D	10.0	pc/mi/ln
Level of service, LOS	A	

Overall results are not computed when free-flow speed is less than 55 mph.

Merge Analysis

Analyst: Tom Hiles
Agency/Co.: HDR Inc.
Date performed: 4/2/2008 9:27:05 AM
Analysis time period: AM
Freeway/Dir of Travel: I-35 Southbound
Junction: 15 Waverly Entr
Jurisdiction: KDOT
Analysis Year: 2030
Description: NEPA Traffic Study

Freeway Data

Type of analysis	Merge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	1320	vph

On Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-flow speed on ramp	35.0	mph
Volume on ramp	120	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent Ramp		vph
Position of adjacent Ramp		
Type of adjacent Ramp		
Distance to adjacent Ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway		Ramp		Adjacent Ramp	
Volume, V (vph)	1320		120			vph
Peak-hour factor, PHF	0.90		0.90			
Peak 15-min volume, v15	367		33			v
Trucks and buses	19		3			%
Recreational vehicles	0		0			%
Terrain type:	Level		Rolling			
Grade		%		%		%
Length		mi		mi		mi
Trucks and buses PCE, ET	1.5*		2.5			
Recreational vehicle PCE, ER	1.2*		2.0			
Heavy vehicle adjustment, fHV	0.913		0.957			
Driver population factor, fP	1.00		1.00			
Flow rate, vp	1606		139			pcph

Estimation of V12 Merge Areas

L_{EQ} = (Equation 25-2 or 25-3)

P_{FM} = 1.000 Using Equation 0

$v_{12} = v_F (P_{FM})$ = 1606 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
v_{FO}	1745	4800	No
v_{3} or v_{av34}	0 pc/h	(Equation 25-4 or 25-5)	
Is v_{3} or v_{av34} > 2700 pc/h?		No	
Is v_{3} or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-8)	

Flow Entering Merge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	1606	4400	No

!

Level of Service Determination (if not F)

Density, $D_R = 5.475 + 0.00734 v_R + 0.0078 v_{12} - 0.00627 L_A$ = 14.0 pc/mi/ln

Level of service for ramp-freeway junction areas of influence B

Speed Estimation

Intermediate speed variable,	M_S = 0.287	
Space mean speed in ramp influence area,	S_R = 62.0	mph
Space mean speed in outer lanes,	S_0 = N/A	mph
Space mean speed for all vehicles,	S = 62.0	mph

Diverge Analysis

Analyst: Tom Hiles
Agency/Co.: HDR Inc.
Date performed: 4/2/2008 9:27:05 AM
Analysis time period: AM
Freeway/Dir of Travel: I-35 Southbound
Junction: 16 Sunflower Exit
Jurisdiction: KDOT
Analysis Year: 2030
Description: NEPA Traffic Study

Freeway Data

Type of analysis	Diverge	
Number of lanes in freeway	2	
Free-flow speed on freeway	70.0	mph
Volume on freeway	1440	vph

Off Ramp Data

Side of freeway	Right	
Number of lanes in ramp	1	
Free-Flow speed on ramp	35.0	mph
Volume on ramp	340	vph
Length of first accel/decel lane	800	ft
Length of second accel/decel lane		ft

Adjacent Ramp Data (if one exists)

Does adjacent ramp exist?	No	
Volume on adjacent ramp		vph
Position of adjacent ramp		
Type of adjacent ramp		
Distance to adjacent ramp		ft

Conversion to pc/h Under Base Conditions

Junction Components	Freeway		Ramp		Adjacent Ramp	
Volume, V (vph)	1440		340			vph
Peak-hour factor, PHF	0.90		0.90			
Peak 15-min volume, v15	400		94			v
Trucks and buses	24		0			%
Recreational vehicles	0		0			%
Terrain type:	Level		Rolling			
Grade	0.00	%	0.00	%		%
Length	0.00	mi	0.00	mi		mi
Trucks and buses PCE, ET	1.5*		2.5			
Recreational vehicle PCE, ER	1.2*		2.0			
Heavy vehicle adjustment, fHV	0.893		1.000			
Driver population factor, fP	1.00		1.00			
Flow rate, vp	1792		378			pcph

Estimation of V12 Diverge Areas

L_{EQ} = (Equation 25-8 or 25-9)

P_{FD} = 1.000 Using Equation 0

$v_{12} = v_R + (v_F - v_R) P_{FD}$ = 1792 pc/h

Capacity Checks

	Actual	Maximum	LOS F?
$v_{Fi} = v_F$	1792	4800	No
$v_{FO} = v_F - v_R$	1414	4800	No
v_R	378	2000	No
v_{3} or v_{av34}	0 pc/h	(Equation 25-15 or 25-16)	
Is v_{3} or v_{av34} > 2700 pc/h?		No	
Is v_{3} or v_{av34} > 1.5 v_{12}/2		No	
If yes, v_{12A} =		(Equation 25-18)	

Flow Entering Diverge Influence Area

	Actual	Max Desirable	Violation?
v_{12}	1792	4600	No

!

Level of Service Determination (if not F)

Density, $D_R = 4.252 + 0.0086 v_{12} - 0.009 L_D$ = 12.5 pc/mi/ln

Level of service for ramp-freeway junction areas of influence B

Speed Estimation

Intermediate speed variable,	D_S = 0.462	
Space mean speed in ramp influence area,	S_R = 57.1	mph
Space mean speed in outer lanes,	S_0 = N/A	mph
Space mean speed for all vehicles,	S = 57.1	mph

Diesel Emissions and Lung Cancer:

Epidemiology and Quantitative Risk Assessment

A Special Report of the Institute's Diesel Epidemiology Expert Panel

Health Effects Institute

June 1999

HEI HEALTH EFFECTS INSTITUTE

The Health Effects Institute, established in 1980, is an independent and unbiased source of information on the health effects of motor vehicle emissions. HEI supports research on all major pollutants, including regulated pollutants (such as carbon monoxide, ozone, nitrogen dioxide, and particulate matter), and unregulated pollutants (such as diesel engine exhaust, methanol, and aldehydes). To date, HEI has supported more than 200 projects at institutions in North America and Europe and published over 100 Research Reports. Consistent with its mission to serve as an independent source of information on the health effects of motor vehicle pollutants, the Institute also engages in special review and evaluation activities.

Typically, HEI receives half its funds from the U.S. Environmental Protection Agency and half from 28 manufacturers and marketers of motor vehicles and engines in the United States. Occasionally, funds from other public or private organizations either support special projects or provide resources for a portion of an HEI study. Regardless of funding sources, HEI exercises complete autonomy in setting its research priorities and in reaching its conclusions. An independent Board of Directors governs HEI. The Institute's Research and Review Committees serve complementary scientific purposes and draw distinguished scientists as members. The results of HEI-funded research and evaluations have been used in public and private decision-making.

Statement from the HEI Board of Directors

Diesel engine technology has played a valuable role in the transportation industry worldwide since the Second World War. Diesel-powered engines are more efficient than gasoline-powered engines, and as a result they emit less carbon dioxide, which is a greenhouse gas. However, diesel engine emissions contain more oxides of nitrogen, which are ozone precursors, and particulate matter than gasoline engine emissions. The impact on human health of inhaling particulate matter, especially in the development of lung cancer, has been a matter of scientific concern and research.

For more than a decade, state, national, and international agencies have spent considerable effort to examine the resulting scientific literature to determine whether diesel engine emissions, and more specifically, diesel particulate matter, is carcinogenic in humans. The majority of the effort has been focused on lung cancer. Regulatory agencies that have a mandate to protect the public's health have examined the biologic, toxicologic, and epidemiologic data to identify the possible carcinogenic hazard from exposure to diesel exhaust and to develop quantitative risk estimates for diesel exhaust exposure and lung cancer. These risk estimates have been controversial.

The Health Effects Institute has supported research on the health effects of exposure to diesel emissions for many years. In the early 1980s, this research, via studies of mutagenicity, metabolism, and carcinogenesis, focused on the organic constituents of diesel exhaust particles. In the late 1980s, a major study compared the carcinogenicity of diesel particles and carbon black in rats, and found very similar results: The carbonaceous particles, not the organic chemicals adsorbed onto the particles, were responsible for the tumor response in rats, which was most likely due to particles overloading the lung clearance mechanism.

In 1995, HEI published a Special Report, *Diesel Exhaust: A Critical Analysis of Emissions, Exposure, and Health Effects*, in which the HEI Diesel Working Group raised questions about the use of animal data for quantitative risk assessment. With respect to epidemiologic studies, the Working Group noted those studies showed consistent, small increases in risk for exposed workers, but concluded that the absence of concurrent exposure measurements limited the utility of those studies for quantitative risk assessment.

As part of the Institute's continued interest in diesel engine emissions and health effects, and in an effort to understand how current research or possible new research could be useful for quantitative risk assessment, HEI initiated the Diesel Epidemiology Project in 1998. This multifaceted effort includes the work of the Diesel Epidemiology Expert Panel (contained in this report), a set of feasibility studies to inform the direction of new research, and the Diesel Workshop: Building a Research Strategy to Improve Risk Assessment, held in March of 1999.

We appointed seven scientific experts in biostatistics, epidemiology, exposure assessment, and exposure characterization as the Diesel Epidemiology Expert Panel to examine specifically the strengths and limitations of the published epidemiologic studies currently available for quantitative risk estimation, and to evaluate discrepancies in the exposure-response findings reported. We have reviewed the report, and the process the Panel used in preparing it, and believe it presents a systematic and fair evaluation of the available epidemiologic studies and the associated quantitative data. The Panel also has identified through its analysis a reasonable explanation for conflicting exposure-response findings previously reported.

We expect that the Panel's review, analyses, and recommendations will be used by HEI and others to address research priorities for further quantitative estimation of the relation between exposure to diesel emissions and lung cancer risk. We also note the need to consider the relation between diesel emissions and noncancer health effects. As the use of diesel fuels around the world expands to take advantage of fuel economy and reduced greenhouse gas emissions, the full range of health effects needs to be considered and weighed along with potential climate change benefits.

In addition to thanking the entire HEI Diesel Epidemiology Expert Panel, we would particularly like to thank Dr. John C. Bailar III, Chair of the Panel, and Dr. Diane J. Mundt, who served as HEI's scientific project manager.

REVIEWERS

This report was submitted for outside peer review. The Health Effects Institute appreciates the thoughtful critiques provided by the reviewers listed below. The views expressed in this report are those of the Diesel Epidemiology Expert Panel and no endorsement by the external reviewers should be inferred.

The Panel extends its gratitude to Aaron Blair, William Bunn, Glen Cass, James Cogliano, Kenny Crump, Stanley Dawson, Eric Garshick, Dale Hattis, Daniel Krewski, Philip Lorang, Frank Mirer, Suresh Moolgavkar, Robert O'Keefe, Jonathan Samet, Michael Spallek, Kyle Steenland, Duncan Thomas, Gerald van Belle, Jane Warren, and Winthrop Watts.

Although this document was produced with partial funding by the United States Environmental Protection Agency under Assistance Agreement 824835 to the Health Effects Institute, it has not been subjected to the Agency's peer and administrative review and therefore may not necessarily reflect the views of the Agency, and no official endorsement should be inferred. The contents of this document also have not been reviewed by private party institutions, including those that support the Health Effects Institute; therefore, it may not reflect the views and policies of those parties, and no endorsement by them should be inferred.

Executive Summary

Diesel engines are an important part of the world's transportation and industrial infrastructure, especially in heavy-duty applications such as trucks, buses, construction and farm equipment, locomotives, and ships. Energy efficiency and durability account for the dominant use of diesel engines worldwide, and their use may expand in the future. In Europe, 20% to 50% of the new light-duty passenger fleet is powered by diesel engines. Although the percentage of diesel-powered light-duty vehicles is much lower in the United States, advanced technology diesel engines are being proposed as part of the nation's energy conservation and climate change strategies.

The economic advantages of diesel engines are clear; nevertheless, environmental concerns and related health issues must be addressed. Emissions from all types of engines are highly variable and complex mixtures. Diesel engines are more efficient than gasoline engines, and they emit less carbon dioxide (a greenhouse gas), carbon monoxide, and hydrocarbons. Therefore, diesel engines have some advantages over conventional gasoline engines in terms of global warming. However, they emit higher levels of oxides of nitrogen, which are ozone precursors, and particulate matter per vehicle mile traveled than do gasoline engines. The particulates are of special concern in possible health outcomes; they are small enough to be readily respirable, and they have many chemicals adsorbed to their surfaces, including known or suspected mutagens and carcinogens.

Cellular, animal, and human studies have investigated the association between exposure to diesel exhaust and adverse health effects, including cancer. Lung tumors have occurred in rats exposed to diesel exhaust, but the relevance of these lesions to human risk assessment has been questioned. Epidemiologic studies fairly consistently show an elevation in lung cancer rates among occupationally exposed individuals. In most studies, rates are 20% to 50% greater than those in unexposed individuals; however, these studies did not obtain quantitative measurements of exposure during the time period of the study.

Although epidemiologic data have been used generally to identify the hazards associated with exposure to diesel exhaust, questions remain as to whether the human data can be used to develop reliable estimates of the magnitude of any risk for lung cancer (that is, through quantitative risk assessment [QRA]), and whether new research efforts could provide any additional data needed. In response to such issues, the Health Effects Institute initiated the Diesel Epidemiology Project in 1998. The Project includes the evaluation by HEI's Diesel Epidemiology Expert Panel of occupational epidemiologic studies that have been used for QRA, and the development of new research initiatives to improve understanding about the health effects of diesel exhaust.

The Diesel Epidemiology Expert Panel was chaired by John C. Bailar, III, M.D., Ph.D., of The University of Chicago and the HEI Review Committee, and included six other scientists who have expertise in epidemiology, biostatistics, exposure characterization, and exposure assessment. It was charged to (1) review the epidemiologic data that form the basis of current QRAs for diesel exhaust, (2) identify data gaps and sources of uncertainty, (3) make recommendations about the usefulness of extending or conducting further analyses of existing data sets, and (4) make recommendations for the design of new studies that would provide a stronger basis for risk assessment.

Although lung cancer was the health outcome of interest to the Panel's charge, it was not charged to evaluate either the broad toxicologic or epidemiologic literature concerning exposure to diesel exhaust and lung cancer for hazard identification purposes, which has been done by others. State, national, and international agencies have all reviewed the broader animal and human evidence for carcinogenicity and, in either their draft or final reports, have all identified diesel exhaust as a probable human carcinogen or placed it in a comparable category (National Institute for Occupational Safety and Health 1988; International Agency for Research on Cancer 1989; World Health Organization 1996; National Toxicology Program 1998; Office of Environmental Health Hazard Assessment [California Environmental Protection Agency] 1998; U.S. Environmental Protection Agency 1998).

In response to the first charge, the Panel examined published epidemiologic studies of diesel exhaust emissions and lung cancer for possible use in support of QRA. Only two such studies reported any quantitative exposure data associated in some manner with the occupational epidemiologic studies, and they were considered in the Panel's review.

The Panel recognized that no epidemiologic study can be perfect. Therefore, the Panel viewed its task as addressing the question: To what extent can limitations in the design and performance of a particular study affect its contribution to the body of epidemiologic knowledge under examination for QRA? The Panel also recognized that frequently it is very difficult to obtain retrospective data for estimating job-related work exposures, and that this process may require assumptions that cannot be validated. In the studies considered here, which form the core of the Panel's review, reasonable attempts were made to reconstruct past exposures to diesel engine emissions using approaches that were feasible when the studies were conducted. These data subsequently have been used, in some cases, for purposes that were not envisioned by the original investigators. The studies reviewed for this report include:

Teamster Studies

- Case-control: Steenland et al. 1990, 1992
- Industrial hygiene: Zaebst et al. 1991
- Exposure-response analysis: Steenland et al. 1998

The reports of these studies were supplemented by published articles and by presentations to the Panel by the principal investigators and others, including secondary analysts of the railroad worker data. The Panel did not consider other completed lung cancer and diesel epidemiologic studies because they included no directly associated quantitative exposure data.

Certain strengths are evident in the studies reviewed by the Panel. The epidemiologic studies include large numbers of study subjects (55,407 subjects, and 1,694 lung cancers, for the railroad worker cohort study; 1,256 deaths from lung cancer for the railroad worker case-control study; and 996 deaths from lung cancer for the teamster case-control study), all of whom were employed in industries where many workers are exposed to diesel exhaust. Job categories with known exposure to asbestos were either excluded or controlled for in the analyses. Both of the case-control studies adjusted data analyses to control for cigarette smoking as a confounding variable. Overall, the results are generally consistent with findings of a weak association between lung cancer and exposure to diesel exhaust. However, published secondary analyses of exposure-response relations in the railroad worker cohort data produced conflicting results (Crump et al. 1991; Office of Environmental Health Hazard Assessment 1998).

Measurements from the industrial hygiene studies in general supported the job exposure categories used in the epidemiologic studies. The industrial hygiene studies measured different markers for diesel exhaust exposure—respirable-sized particles (RSP) for railroad workers and submicron-sized elemental carbon (EC_1) for teamsters. Although the RSP measures were adjusted for the environmental tobacco smoke component, EC_1 is more sensitive and specific to diesel exhaust than adjusted RSP.

In response to the second charge, the Panel developed a framework of general epidemiologic questions about study design, exposure assessment, outcome determination, and analysis. These are meant to help in systematically understanding and revealing the strengths and uncertainties of these studies. This framework was then used to evaluate the studies of railroad workers and teamsters. This process helped to address the third and fourth charges to the Panel, and to assist HEI in focusing its future research directions to inform apparent gaps for QRA.

The original findings of the cohort railroad worker study reported by Garshick and coworkers (1988) indicated a steadily increasing risk of lung cancer for exposed workers with increasing years of employment. This increase with duration of employment, however, was not supported in later, unpublished analyses (Garshick 1991). This increasing risk, plus the availability of some quantitative exposure data in railroad workers (Woskie et al. 1988a,b), prompted additional analyses to explore the exposure-response relation in these data (Crump et al. 1991; Office of Environmental Health Hazard Assessment 1994, 1998; Crump 1999). Crump and colleagues found a negative association between lung cancer risk and several measures of cumulative exposure; that is, risk decreased with increasing cumulative exposure. In contrast, the statistical models used by the Office of Environmental Health Hazard Assessment analysts, using the same data but different assumptions, showed a positive association in which risk increased with increasing cumulative exposure.

The Panel explored these apparent inconsistencies in the exposure-response relation to verify and obtain a better understanding of the previous analyses, and to help clarify differences. These issues are central to whether the railroad worker data can be useful in a QRA for lung cancer.

The Panel's data exploration demonstrated that within the three broad railroad job categories of train workers (e.g., engineers, conductors), shop workers (e.g., electricians, machinists), and clerks and signalmen, the relative risk of lung cancer decreased with increasing duration of employment, and this decrease was statistically significant for the clerks/signalmen and train workers. Although the relative risk decreased with increasing duration of employment, overall risks for train workers, within each duration of employment group, were higher than those for clerks and signalmen, and shop workers had intermediate risks (Figure 1).

These findings are not consistent with a steadily increasing association between cumulative diesel exposure and lung cancer risk. Furthermore, if the difference in risk between train workers and clerks/signalmen was due primarily to differences in exposure to diesel emissions, one would expect the relative risk for train workers compared with that for clerks and signalmen to be reduced or even eliminated after adjusting for exposure. In fact, adjustment for exposure increased this relative risk. Such a systematic pattern of decreasing risk with increasing exposure suggests that some form of bias is present in the data, which makes it difficult to determine the true nature of an exposure-response relation. Bias can result from uncontrolled confounding by cigarette smoking or by other occupational exposure, differential misclassification of exposures by job category, longer survival of "healthier" workers, or differential ascertainment of lung cancer as a cause of death.

Initial findings from the teamster case-control study (Steenland et al. 1990) showed an increased risk of lung cancer with increasing years of employment. The investigators published an exposure-response analysis for the teamster study (Steenland et al. 1998) after the Panel's work started, thus the evaluation of this set of studies was necessarily less extensive.

Reconstructing past exposures for which actual data are limited or nonexistent requires several assumptions. The Panel had concerns about several of the assumptions used by Steenland and colleagues in the exposure-response analysis of the teamster data. These concerns include (1) the data on 1990 emissions used to estimate past exposures to diesel exhaust may underestimate average exposures over a range of work histories, given that more recent data show higher emissions for that time; (2) the date assumed for dieselization in the trucking industry, which, if too early, may overestimate exposures; (3) the degree to which vehicle miles traveled accurately reflects actual exposure to diesel exhaust for various job groups, which may affect exposure estimates in either direction; (4) the possible effects of using various scenarios of emission levels to account for long fleet turnover times in the trucking industry; and (5) the difficulty in distinguishing truck driver exposures from background levels, because measured estimates are close. Also, among the assumptions Steenland and colleagues used, nondiesel sources of elemental carbon in ambient air, especially from gasoline engine emissions, were not considered.

The Panel also was concerned about the controls used in the case-control study. Lung and bladder cancers and motor vehicle accidents were excluded as control causes of death, and controls were selected from other causes. If those causes of death were associated with exposure to diesel emissions, smoking, or both, the study findings could be biased.

Important work is currently under way to study the health effects of exposure to diesel exhaust in nonmetal miners in Germany (Säverin et al. 1998) and in the United States (National Cancer Institute–National Institute for Occupational Safety and Health 1997). The Panel did not review these studies because they are still in progress. However, the Panel heard presentations from these investigators at the HEI Diesel Workshop: Building a Research Strategy to Improve Risk Assessment (HEI 1999) at Stone Mountain, GA, March 7–9, 1999. In particular, the National Cancer Institute–National Institute for Occupational Safety and Health study is large and appears to be well designed and comprehensive. It includes a cohort and nested case-control component, as well as extensive current measurements of exposure to diesel exhaust, detailed reconstruction of historical exposure, and bio-

Figure 1. Panel's analysis depicting consistently elevated risk of lung cancer for train workers compared with clerks for each time period, but decreasing risk by job category over duration of employment. See Appendix C for details.

marker development. These studies in progress are likely to inform hazard identification, exposure estimation, and exposure-response analyses, all components of risk assessment.

The Panel recognizes that regulatory decisions need to be made in spite of the limitations and uncertainties of the few studies with quantitative data currently available. The findings described here and the systematic evaluation of these and other studies are designed to inform the ongoing process and provide a means to weigh a study's strengths and limitations.

FINDINGS

GENERAL

Enhanced exposure and epidemiologic data and analyses are needed for the purposes of QRA; these might come from further exploration of existing studies or from new studies.

RAILROAD WORKER STUDIES

At present, the railroad worker cohort study (Garshick et al. 1988), though part of a larger body of hazard identification studies, has very limited utility for QRA of lifetime lung cancer risk from exposure to ambient levels of diesel exhaust for the following reasons.

- The various exposure-response analyses are limited by the scope and quality of currently available exposure data. Quantitative exposure data were not obtained during the cohort study period. Also, there is a paucity of qualitative data on individual exposures before 1959, and on the variation in exposure by railroad site, by season, and over time. The potential impact of concurrent exposures (for example, to grease, dust, other fumes, asbestos, and active and passive cigarette smoke) were not examined in depth. The diesel exhaust exposure data are suitable for a crude categorical measure of exposure by job category; but other measures, including duration of employment in a job category exposed to diesel exhaust, intensity of exposure concentration ($\mu g/m^3$), and lifetime exposure ($[\mu g/m^3]$-years), are not adequate to support quantitative exposure-response analyses.
- The Panel's analysis of the exposure-response association in the railroad worker data showed that the evidence for a positive association of lung cancer with cumulative exposure to diesel exhaust depends entirely on differences in risks among job categories. Train workers (with higher exposures) have higher risks compared with clerks (with low or no exposure). However, within all job categories, the relation of lung cancer risk to duration of employment is negative.
- Factors that might explain a negative association between duration of employment and lung cancer in these data include bias introduced by systematic differences in exposure misclassification among and within job categories; differentially incomplete ascertainment of lung cancer deaths by job category; lack of information on other occupational exposures and air pollutants; the presence of a healthy worker survivor effect; confounding by cigarette smoking; and analysis of relative risks rather than absolute risks. Also, in a case-control study, if causes of death among controls were associated with exposure to diesel exhaust, smoking, or both, the results could be biased.

TEAMSTER STUDIES

The investigators' analysis of the teamster data reported an exposure-response relation (Steenland et al. 1998) that may be useful for QRA; this relation will be better understood with further exploration of uncertainties and assumptions, particularly those relating to the reconstruction of past exposures and the selection of controls. Exposures of teamsters are more similar to ambient exposures of the public than are exposures of railroad workers, and the diesel exhaust to which teamsters are exposed comes from a source that is likely to be relevant to regulatory issues.

The Panel reviewed the teamster study without the benefit of additional analyses and interpretations, and its comments are not as detailed as those about the railroad worker studies. Understanding the teamster study will evolve with time; however, some conclusions can be drawn now.

- The set of teamster studies may provide reasonable estimates of worker exposure to diesel exhaust, but significant further evaluation and development are needed. The marker for diesel exhaust that was selected for study by Steenland and associates, EC_1, is more sensitive and specific than RSP adjusted for environmental tobacco smoke, but has several limitations (e.g., the contribution of diesel emissions to ambient EC_1 concentrations has not been constant over time). The industrial hygiene study, which was conducted after the period when workers in the case-control study were exposed, identified a range of exposures for various job categories, but did not consider (1) site-to-site variations, (2) seasonal variations, (3) concurrent exposures to other agents, (4) historical ambient particle concentrations, or (5) intra- and interindividual variability. The estimation of historical exposures needs to incorporate recent data on diesel emissions from vehicles in use, reassessment of when dieselization occurred, alternatives to estimating exposure by vehicle miles traveled, and historical regional ambient pollution data.

- The exposure-response relation reported in the teamster study increases in a linear manner. However, more can be learned from other analysts examining these data using different approaches.
- Neither a roster of the study population nor an alternative method of selecting controls to represent it was available to the researchers. It cannot be established with certainty whether the causes of death used for controls adequately represent the joint distribution of exposure to diesel exhaust and smoking in the case-control study. If smoking, or diesel exhaust exposure as determined by job category, or both were associated with causes of death used for controls, results could be biased.

RECOMMENDATIONS

The Panel's recommendations reflect its general understanding, as expressed in its framework for evaluating studies, of what constitute adequate data for QRA. They also reflect the preceding evaluation of the studies of railroad workers and teamsters. The Panel is aware that research currently in progress will respond to some of these research needs; however, results are not yet available, and it is not yet clear whether all of the proposed needs will be met.

COMPLETED STUDIES

1. The Panel recommends against using the current railroad worker data as the basis for QRA in ambient settings.
2. Further scrutiny of the teamster data, including estimation of uncertainty in both the exposure estimates and selection of controls, is recommended in order to improve the use of these data in QRA. Strengths of the teamster study include the relevance of exposure levels to the general population and the use of an exposure marker for diesel engine emissions that was an improvement over RSP. The teamster study exposure-response analysis is relatively new, and its further review and analysis by both the original investigators and others should be accelerated. Alternative retrospective exposure models need to be developed that use the alternative assumptions described above and in more detail in the body of the text.

NEEDS FOR NEW TECHNIQUES AND DATA

3. Better measures of exposure to constituents of diesel emissions, with careful attention to selection of the sample studied, are needed. Of particular importance are the selection and validation of a chemical marker of exposure to the complex mix of diesel exhaust emissions. Exposure models may include data from personal monitors, area monitors placed where diesel exposure is likely to occur, and current and historical data regarding emission sources. In any such modeling effort, the effects of environmental tobacco smoke should be removed as completely as possible.
4. Reliable estimates of past emissions and of factors affecting historical exposures in a range of settings are needed to improve the characterization of uncertainties, both quantitative and qualitative, in historical models of exposures.
5. Although biomarker technology was not available when the studies reviewed were conducted, appropriate, validated, and specific biomarkers of diesel exposures, health outcomes, and susceptibility are needed.

DESIGN NEEDS FOR NEW STUDIES OF EXPOSURE-RESPONSE ANALYSES

6. Exposures should be adequately and accurately characterized with respect to magnitude, frequency, and duration, rather than solely by duration of employment. Errors and uncertainties in exposure measurements should be quantified where possible; these should be fully reported to users, and taken into account in both power calculations and exposure-response analyses.
7. Cigarette smoking is a potent risk factor for lung cancer, and it must be controlled for in any study of risk factors for this disease. Smoking histories obtained for a cohort study subset that uses a case-control or case-cohort design will strengthen the interpretation of results.
8. The exposures considered should be close to levels of regulatory concern, including a range of exposures to provide a base for understanding the relation between exposure and health effects.

NEEDS FOR NEW STUDIES

A prospective epidemiologic study of the development of lung cancer in exposed and unexposed individuals could have many strengths. Information on confounders and exposures could be more complete than for a retrospective study, and many of the biases and uncertainties discussed in this report could be eliminated or reduced. These advantages, however, need to be weighed against the disadvantages, which include high costs and a long period of follow-up. Other study designs that include retrospective components are possible for a new epidemiologic study of lung cancer, but they are likely to include uncertainties and sources of bias that investigators will need to explore completely and acknowledge in their reporting.

9. The Panel recommends that a new, large, epidemiologic study of diesel exhaust emissions and lung cancer be considered after (1) currently ongoing or existing studies, including HEI's feasibility studies (to be completed in the spring of 2000), are evaluated, and (2) attempts to retrofit improved exposure assessments to existing epidemiologic studies are evaluated, including whether they can provide sufficiently accurate, complete, and relevant exposure data to support QRA.
10. Studies of lung cancer risk in general populations exposed to ambient diesel exhaust particulate matter will be difficult to conduct; however, such studies could usefully investigate other, noncancer health effects that occur in a shorter time after exposure.

Diesel Emissions and Lung Cancer: Epidemiology and Quantitative Risk Assessment

Background

Diesel engines are an important part of the world's transportation and industrial infrastructure, especially in heavy-duty machinery such as trucks, buses, construction and farm equipment, locomotives, and ships. The use of diesel engines may expand in the future because they are energy-efficient and durable.

In Europe, where fuel prices are three to four times higher than in the United States and concern for climate change is high, 20% to 50% of the new light-duty passenger fleet is powered by diesel engines. In 1996, 1.8% of the light-duty vehicles (passenger cars, light-duty trucks [up to 10,000 pounds gross vehicle weight], vans, and sport utility vehicles) sold in the U.S. were diesel-powered, almost all of which were light-duty trucks. Of all the light-duty trucks sold that year, about 3.7% were diesel-powered; whereas only about 0.1% of all passenger cars sold had diesel engines (Davis 1998). Advanced technology diesel engines are being proposed as key elements in the U.S. energy conservation strategy (e.g., for use in sport utility vehicles and in the Partnership for a New Generation of Vehicles' fuel-efficient car).

Although diesel engines have economic advantages, environmental issues must be considered. Emissions from all types of engines are highly variable and complex mixtures. Diesel engines are more efficient (per vehicle mile traveled) than gasoline engines and emit less carbon dioxide (a greenhouse gas), carbon monoxide, and hydrocarbons; however, they emit more oxides of nitrogen, which are ozone precursors, and particulate matter. It is difficult to estimate exposures to individual constituents of diesel engine emissions because the amount and concentration of each constituent depend on such factors as engine type, fuel, and operating conditions. Moreover, fuel reformulation and changes in engine technology have caused substantial changes in diesel emissions over time. In addition, it is challenging to distinguish diesel emission constituents in ambient air from other combustion products and cigarette smoke.

The particulates emitted in diesel exhaust are of special concern in possible health outcomes because (1) they are very small (less than 1 µm in size) and readily respirable, and (2) they have many chemicals adsorbed to their surfaces, including some known or suspected mutagens and carcinogens. Cellular, animal, and human studies have investigated the association between exposure to diesel exhaust and cancer and other diseases.

DIESEL EXHAUST AND LUNG CANCER

Scientists have conducted toxicologic and epidemiologic studies to examine the potential for diesel emissions to cause or contribute to the development of cancer and other diseases. Some studies have looked specifically at the particulate matter component of diesel emissions; others refer simply to "diesel exhaust." In this report, diesel particulate matter (DPM) is specified when applicable. Laboratory studies have established that lifelong exposures to high concentrations of DPM produce lung tumors (benign and malignant) in rats, equivocal results in mice, and no tumors in hamsters. The roles that high-dose exposure protocols and species-specific factors have in the induction of rat lung tumors by DPM have been investigated. (This material is reviewed in publications by HEI [1995], the World Health Organization [WHO] [1996], and the International Life Sciences Institute [ILSI] [1999]). Rats develop lung tumors (benign and malignant) when they are exposed to DPM at concentrations of 2,000 to 10,000 $\mu g/m^3$ for 35 hours or more each week over their lifetimes (HEI 1995). Prolonged exposure to high concentrations of a variety of other supposedly inert particulate materials also causes lung tumors in rats through a mechanism that involves impairment of lung clearance mechanisms (referred to as "lung overload response"). This impairment can lead to inflammation, cell proliferation, metaplasia, and ultimately the development of lung tumors (HEI 1995; ILSI 1999). The levels of DPM required to produce lung tumors in rats, however, are approximately three orders of magnitude higher than current estimates of average ambient (nonoccupational) concentrations of DPM. Because lung overload is not expected to occur in humans as a result of ambient or most occupational exposures to DPM, some organizations have suggested that the rat lung tumor response to high concentrations of particulate matter is not relevant for quantitative risk assessment (QRA) (HEI 1995; ILSI 1999).

More than 40 epidemiologic studies of workers have examined the association between exposure to diesel exhaust and the risk of lung cancer. Several review articles discuss this literature in depth (Cohen and Higgins 1995; WHO 1996; Boffetta 1997; Bhatia et al. 1998; Office of Health Hazard Assessment [OEHHA] 1998; U.S. Environmental Protection Agency [EPA] 1998). The epidemiologic studies generally show higher risks of lung cancer among persons occupationally exposed to diesel exhaust than among persons who have not been exposed, or who have been exposed to lower levels or for shorter periods of time. Occupational groups studied include railroad workers, truck drivers, bus garage workers, heavy equipment operators, dock workers, and underground miners. In these studies, the relative risk (RR), as a measure of association between exposure and lung cancer, generally has been between 1.2 and 1.5 (that is, an excess of 20% to 50% over the risk in unexposed persons); somewhat more variation in relative risk was reported among subgroups examined in individual studies. Some reviews critical of these data have cited study design flaws, including uncontrolled confounding and lack of exposure measures, leading to a lack of convincing evidence (Muscat and Wynder 1995; Stöber and Abel 1996; Morgan et al. 1997).

Two studies are under way to evaluate the association between exposure to diesel emissions and lung cancer among nonmetal miners in Germany (Säverin et al. 1998) and in the United States (National Cancer Institute–National Institute for Occupational Safety and Health [NCI-NIOSH] 1997). Some results of the former study are available now; those of the latter study are expected in about 2003.

RISK ASSESSMENTS OF DIESEL EMISSIONS

Several organizations have reviewed the relevant science, including the epidemiologic, toxicologic, and experimental studies of diesel engine exhaust, and have classified (or proposed to classify) the exhaust mixture, or the particulate component of the mixture, as a potential, probable, or definite human carcinogen (NIOSH 1988; International Agency for Research on Cancer [IARC] 1989; WHO 1996; OEHHA 1998; National Toxicology Program [NTP] 1998; U.S. EPA 1998). Each agency's current position on the carcinogenicity of diesel exhaust as cited in its draft or final report is as follows:

NIOSH (1988)

- Animal evidence "confirmatory" for carcinogenicity
- Human evidence "limited"
- Diesel exhaust classified as a "potential occupational carcinogen"
- No QRA

IARC (1989)

- Rat data "sufficient" for carcinogenicity
- Human epidemiologic data "limited"
- Diesel exhaust considered a "probable" human carcinogen
- No QRA

WHO (1996)

- Rat data support carcinogenicity
- Human epidemiologic data suggest "probably carcinogenic"
- Epidemiologic studies considered "inadequate for a quantitative estimate of human risk"
- Rat data used for QRA

California EPA (1998)

- Rat data "have demonstrated" carcinogenicity of diesel exhaust
- Causal association of diesel exhaust and lung cancer in epidemiologic studies is a "reasonable and likely explanation"
- Human epidemiologic data preferred for QRA because of uncertainties in rat data
- California Air Resources Board designated DPM a "toxic air contaminant"

NTP (1998 Draft)

- Committees have considered listing DPM as either "known to be a carcinogen" or "reasonably anticipated to be a carcinogen"
- Internal review complete; Directors' decision expected in 1999

U.S. EPA (1998 Draft)

- Rat experiments "adequate" for carcinogenicity
- Human epidemiologic studies "limited" evidence
- Diesel emissions considered "probable" human carcinogen
- Range of cancer risk estimates developed (on the basis of animal, epidemiologic, and comparative potency data)
- Revised risk assessment expected in 1999

In 1994, the U.S. EPA and the California EPA both released draft cancer risk assessments of diesel exhaust for public comment and review by scientific experts. Despite general agreement in their interpretation of the scientific literature, some important differences were apparent between the two reports. Most notably, the basis for the U.S. EPA's QRA was animal bioassay data because, in the view of the Agency's staff, the exposure data from human epidemiologic studies were too limited to support a QRA. In addition, the U.S. EPA staff, in conjunction with Dr. Kenny Crump, had tried to use data from a retrospective cohort study of U.S. railroad workers (Garshick et al. 1988) and an associated industrial hygiene survey (Hammond et al. 1988; Woskie et al. 1988a,b) to construct exposure-response estimates (Crump et al. 1991). Crump and colleagues did not find a positive exposure-response association for diesel exhaust and risk of lung cancer, however, and therefore concluded that it was not possible to use these data for a quantitative analysis.

In contrast, staff in the OEHHA of the California EPA, using the same railroad worker data, found an increasing exposure-response relationship (OEHHA 1994, 1998). Because of uncertainties in extrapolating from rat data to humans and the fact that some semiquantitative epidemiologic data were available, OEHHA determined that it was more appropriate to base risk assessment estimates for diesel exhaust on the epidemiologic data than on animal data.

The difference between these findings led HEI in 1996 to collaborate with the two agencies and others (NIOSH and WHO) to sponsor a scientific workshop, "Diesel Exhaust: Considerations in the Use of Epidemiologic Data for Quantitative Risk Assessments (QRA)," that focused on the strengths and limitations of the existing database. Participants discussed issues that underlie the differences in the exposure-response modeling of the railroad worker data. Although the findings were explored at length, workshop participants were unable to determine the reasons for the differences. The railroad worker data were the only epidemiologic data used in QRA until Steenland and colleagues (1998) published an exposure-response analysis of U.S. teamsters.

Questions still remain about how to develop a reliable QRA of diesel engine emissions and lung cancer. If the rat lung tumor data are not relevant for human cancer risk assessment, and if current epidemiologic studies do not provide the quantitative exposure measurements needed for exposure-response estimates, it is difficult to make informed decisions about possible health risks from exposure to diesel exhaust. Should existing epidemiologic studies be extended to include additional years of follow-up? Have diesel engines and fuels changed so much that studies of animals or humans exposed to diesel exhaust from old engines are no longer relevant? Government, industry, and the public have an interest in answers to these questions. HEI initiated its Diesel Epidemiology Project to help inform the decisions about appropriate ways to use the existing epidemiologic data and to suggest future research directions.

The HEI Diesel Epidemiology Project

In 1998, HEI initiated a multifaceted Diesel Epidemiology Project in response to the issues discussed in the Background chapter. This project includes the evaluation by HEI's Diesel Epidemiology Expert Panel of occupational epidemiologic studies that are currently being used for QRA, and the development of new research initiatives, including six feasibility studies to identify potential new cohorts to study or to improve exposure assessment estimates.

The Diesel Epidemiology Expert Panel (referred to here as "the Panel") was chaired by John C. Bailar III, M.D., Ph.D., of The University of Chicago and the HEI Health Review Committee, and included six other members (see Appendix A) with expertise in epidemiology, biostatistics, exposure characterization, and exposure assessment. Its charge was to (1) review the epidemiologic data that form the basis of current QRAs for diesel exhaust, (2) identify data gaps and sources of uncertainty, (3) make recommendations about the usefulness of extending or conducting further analyses of existing data sets, and (4) make recommendations for the design of new studies that would provide a stronger basis for risk assessment. The Panel was not charged to evaluate the broad epidemiologic literature concerning exposure to diesel exhaust and lung cancer for hazard identification purposes.

In response to the first charge, the Panel examined published epidemiologic studies for possible use in or contribution to QRA for diesel exhaust. However, quantitative exposure data were associated in some manner with only two epidemiologic studies, and those are considered in this report. Other diesel epidemiologic studies were not considered, because the lack of associated quantitative exposure data makes those studies less suitable for QRA. The studies forming the core of the Panel's review include:

Railroad Worker Studies

- Case-control: Garshick et al. 1987
- Cohort: Garshick et al. 1988
- Industrial hygiene: Hammond 1988, and Woskie et al. 1988a,b
- Exposure-response analyses: Crump et al. 1991, OEHHA 1998, and Crump 1999

Teamster Studies

- Case-control: Steenland et al. 1990, 1992
- Industrial hygiene: Zaebst et al. 1991
- Exposure-response analysis: Steenland et al. 1998

The Panel met on April 20–21, 1998, in Cambridge, MA, to hear presentations by the principal investigators of the epidemiologic studies listed above, and by the secondary analysts of the railroad worker cohort study. The Panel also began discussing how to approach its charge. An agenda for the workshop portion of the April 1998 meeting and a list of participants are in Appendix A. The Panel met in executive session on October 8–9, 1998; December 1, 1998; January 21, 1999; and by conference call on February 24 and April 9, 1999, to continue its work on this report.

At the first meeting of the Panel, inconsistent results of the exposure-response analysis of the railroad worker cohort data were presented by the secondary analysts. The Panel determined that it would need to explore the exposure-response relation in the original railroad worker data set in order to understand firsthand the reasons for the discrepancies. The Panel did not attempt to conduct its own exposure-response analysis for QRA. Eric Garshick, M.D., assisted the Panel by providing a copy of the original railroad worker data and documentation. Secondary analyst Stanley Dawson, Ph.D., of California EPA's OEHHA, provided documentation of his analysis of the original data set; likewise, Kenny Crump, Ph.D., provided the computer code listings he used for aggregating the original railroad worker data. The Panel is grateful to all these analysts for their cooperation and generosity in supporting this review.

THE PANEL'S APPROACH TO EVALUATING THE STUDIES

Epidemiologic studies of environmental pollutants and cancer are relevant to risk assessment, which includes some or all of the following steps: hazard identification (determination of whether or not an agent is causally linked to a health effect), exposure assessment (degree, timing, and level of exposure), dose-response assessment

Table 1. The Panel's Framework for Evaluating Epidemiologic Studies for Quantitative Risk Assessment

Element of Study		Questions for Evaluation
DESIGN	1.	Was the study design efficient, and did it specifically consider power, potential types of bias, and latency?
	2.	Were adequate quantitative exposure and covariate data planned and collected?
	3.	Was the literature reviewed for relevant study methods and previous research findings?
	4.	Were plans made for postpublication data scrutiny?
EXPOSURE ASSESSMENT	1.	Were detailed lifetime histories of occupational exposures collected?
	2.	Were known chemical and physical characteristics of the main exposure specified?
	3.	Were potentially confounding exposures measured or estimated?
	4.	Were magnitude, duration, and variability of exposure determined?
	5.	Were industrial hygiene data and historical data on use and repair of machinery and equipment obtained?
	6.	Were personal exposure measurements obtained, and were they representative of the population studied?
	7.	Were uncertainties in exposure assessment quantified?
OUTCOMES	1.	Were outcomes defined in specific and objective terms?
	2.	Was the full range of outcomes included in cohort studies?
	3.	Were participants actively followed to determine outcome status and the date outcome occurred?
ANALYSIS	1.	Were analytic methods specified a priori?
	2.	Was the appropriateness of the statistical approach demonstrated, and were potential biases explored?
	3.	Were exposure-response relations statistically explored?
	4.	Were uncertainties in risk estimates quantified, especially those resulting from exposure measurement error?

(determination of the relation between the magnitude of exposure and the health effect, including in subpopulations), and risk characterization (description of the nature and magnitude of risk, with uncertainties) (National Academy of Sciences 1983).

All of the characteristics that make a study relevant to hazard identification also help make a study relevant for QRA. But QRA requires more, including quantitative exposure data expressed in units that are comparable among the epidemiologic settings and the situations for which the risk estimates are desired. The quantitative data must be sufficient to construct an exposure-response curve on the basis of at least two levels of exposure. Occupational exposure levels often are much greater than ambient (nonoccupational) exposures. When occupational studies are used in a QRA that is to be extended to populations receiving ambient exposures, the analysts may need to extrapolate over a range from the high exposures observed to the lower exposures of interest; the closer the occupational exposures are to the ambient exposures of concern, the less extrapolation is required.

An important limitation of using most epidemiologic studies for QRA is the lack of adequate exposure data, especially historical information on exposure concentrations or rates. In retrospective studies, exposure assessment is almost always less than ideal; the problems and uncertainties in using such data need to be clearly acknowledged.

The Panel recognized that few, if any, studies are designed specifically for use in QRA. It determined that the most objective way to identify data gaps and sources of uncertainty was to systematically review the epidemiologic studies of railroad workers and teamsters*. To guide this process, the Panel developed a framework of general epidemiologic principles, described in Table 1.

This framework presents a series of questions about elements of study design, exposure assessment, outcome determination, and analysis that the Panel determined to be important for this evaluation. An affirmative answer to all questions is clearly unattainable for any epidemiologic study. The answers, however, not only highlight the strengths and limitations of each study, but also indicate where to focus additional or new research efforts. A rationale for including each of the items in the framework is detailed in Appendix B.

A draft version of this entire report was peer-reviewed by 18 external reviewers, including Drs. Garshick, Crump, and Dawson. All of the reviewer comments and concerns were considered and addressed as appropriate by the Panel. Preliminary, draft findings were presented by Panel members at HEI's Diesel Workshop: Building a Research Strategy to Improve Risk Assessment (1999), held at Stone Mountain, GA, March 7–9, 1999.

* The reference to "railroad worker study or studies" in the report refers specifically to the studies by Garshick and colleagues (1987, 1988) and, if appropriate, to the industrial hygiene studies by Woskie and associates (1988a,b) and Hammond (1988). The reference to "teamster study or studies" in the report is specific to the case-control study by Steenland and coworkers (1990), subsequent reports based on these data (Steenland et al. 1992, 1998) and, if appropriate, to the industrial hygiene study by Zaebst and associates (1991).

Summary of Railroad Worker and Teamster Studies

Two sets of studies widely cited as "key" or "important" epidemiologic investigations of diesel exhaust and lung cancer have been used for QRA. One set of studies includes cohort (Garshick et al. 1988) and case-control (Garshick et al. 1987) studies of railroad workers, industrial hygiene measures in railroad work sites (Woskie et al. 1988a,b; Hammond et al. 1988), and secondary exposure-response analyses of these data (Crump et al. 1991; OEHHA 1994, 1998; Crump 1999). The second set includes a case-control study of teamsters (Steenland et al. 1990, 1992), industrial hygiene measures in the trucking industry (Zaebst et al. 1991), and a recent exposure-response analysis (Steenland et al. 1998). This chapter briefly summarizes each study's methods and results.

RAILROAD WORKER STUDIES

Garshick and colleagues conducted both cohort (Garshick et al. 1988) and case-control (Garshick et al. 1987) studies of lung cancer deaths among U.S. railroad workers registered with the Railroad Retirement Board (RRB). The authors' background materials report that the U.S. railroad industry began introducing large numbers of diesel engines in about 1949; dieselization of the industry was essentially completed within 10 years. Figure 2 shows the transition from the use of steam (mostly coal-fired) to diesel locomotives over time (Railroad Facts 1940–1970). In both studies, Garshick and colleagues defined four diesel exhaust exposure groups: shop workers; engineers and firemen; brakemen, conductors, and hostlers; and unexposed (clerks and signalmen).

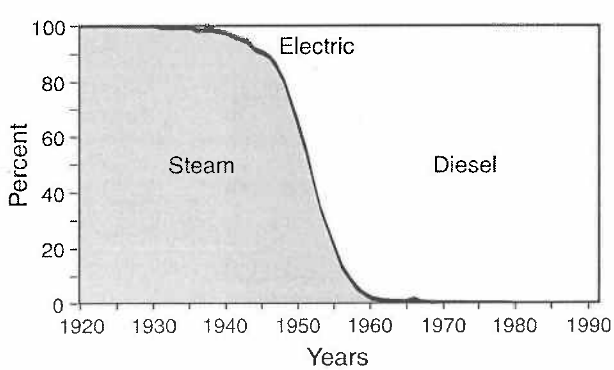

Figure 2. Percentage of trains powered by steam, electric, or diesel since 1920. (Data adapted from Railroad Facts 1940, 1944, 1946, 1948, 1950, 1953, 1954, 1957, 1964, 1967, 1970.)

COHORT STUDY

In the cohort study, Garshick and colleagues (1988) reported that they ascertained all deaths from 1959 to 1980 in a cohort of 55,407 white male railroad workers who had been actively employed and between 40 and 64 years of age in 1959, when nationwide conversion to diesel railway engines was nearly complete. Eligible subjects had begun work 10 to 20 years earlier (between 1939 and 1949), and in 1959, were employed in one of 39 jobs surveyed later in a companion industrial hygiene study (Woskie 1988a,b). Railroad Retirement Board records listed each person's job title, or titles, for each year starting in 1959. To reduce the potential for confounding by asbestos exposure, all workers whose jobs involved known exposure to asbestos (car repair and construction trade workers, and some trade workers in steam locomotive shops) were excluded from the cohort. Some shop workers and hostlers, not initially excluded, were also exposed to asbestos. Cigarette smoking information was not available for cohort members.

Fact of death was ascertained from the RRB through December 31, 1980. Among the 19,396 known deaths, 1,694 of the death certificates indicated lung cancer as a primary or contributing cause of death.

The investigators classified the workers' exposures according to the job held in 1959 or the cumulative years in an exposed job. Their analytic model including years of exposure to diesel exhaust (on the basis of duration of employment) and lung cancer showed an increase in risk of lung cancer with more years of exposure. The investigators also reported that 94% of the workers who were 40 to 44 years of age and working in a job exposed to diesel emissions in 1959 were still in an exposed job 20 years later. Unexposed workers also generally remained in their exposure category (97%). The relative risks for lung cancer and exposure to diesel exhaust on the basis of the job held in 1959 were inversely related to age in 1959; workers who were 40 to 44 years of age and working in a job category with exposure to diesel emissions in 1959 experienced an increase (RR = 1.5; 95% CI: 1.1, 1.9) in lung cancer mortality compared with those who were in that age category but held unexposed jobs in 1959. Excess relative risk of death from lung cancer declined as the worker's age in 1959 increased.

CASE-CONTROL STUDY

Garshick and colleagues (1987) also conducted a case-control study of RRB registrants who died between March 1, 1981, and February 28, 1982. Among 650,000 active and retired male railroad workers born in or after 1900 who had at least 10 years of railroad employment, 15,059 deaths were reported to the RRB. Cases consisted of all deaths for which primary lung cancer (International Classification of Disease, Version 8 [ICD 8] code 162) was indicated on the death certificate; this was the underlying cause of death in most cases. Investigators attempted to match each case with two deceased control subjects by age at death (within 2.5 years), and by date of death (within 31 days). Men who died from other cancers, suicides, accidents, or unknown causes were excluded as control subjects. The most common underlying causes of death among both older (age at death 65 years or older) and younger (age at death 64 years or younger) controls were diseases of the circulatory system (74% and 80%, respectively); deaths from nonmalignant respiratory disease also were included (15% of the older control subjects and 7% of younger controls). Overall, 1,256 lung cancer cases and 2,385 controls were considered in the analysis.

Exposure to diesel exhaust was assessed using (1) job histories beginning in 1959 for workers who retired after 1959, and (2) the last job worked before retirement for those who retired between 1955 and 1959. Each job was classified either as exposed or unexposed; cumulative exposure to diesel exhaust was summarized for each worker as diesel-years of exposure. Unlike the cohort study, the case-control study included persons who had worked in jobs other than the 39 jobs used to estimate diesel exhaust exposure levels in the industrial hygiene survey (Woskie et al. 1988a,b). These additional jobs were considered to be exposed or unexposed on the basis of (1) the similarity of job activities and work locations in question to jobs for which industrial hygiene samples had been taken, and (2) the extent of contact with operating diesel equipment that the job entailed.

Information on two potentially confounding variables (smoking and asbestos exposure) was collected. For smoking history, next of kin (usually a spouse) provided information on whether the subject had ever smoked; this information was obtained for 86% of cases and 82% of control subjects. If the age at which a worker began smoking was not available (which was true for less than 6% of both cases and controls), age 16 was assumed. Pack-years* of smoking history were missing for 22% of cases and 25% of controls. Asbestos exposure was ascertained from the work histories of those who retired after 1959 and from the last job held for those who retired between 1955 and 1959.

The investigators conducted separate analyses for younger workers (who died at or before age 64) and older workers (who died at age 65 or older), primarily because they reasoned that heavy cumulative exposure to diesel exhaust was more likely among the workers who died at a younger age. A second reason was attributed to a cited reference (Doll and Peto 1981) that indicated that the cause of death on a death certificate may be less accurate for workers who died at an older age. No excess risk of death from lung cancer in association with exposure to diesel exhaust was observed among the older workers. Among the younger workers, with diesel exposure modeled as a continuous variable, more than 20 years of exposure to diesel exhaust was associated with a crude RR = 1.4 (95% CI: 1.0, 1.8) for lung cancer mortality. Adjusting for asbestos and cigarette smoking had little effect on this estimate (RR = 1.4; 95% CI: 1.1, 1.9). Among younger workers, when years of diesel exposure were categorized (0–4, 5–19, 20+), an adjusted RR = 1.02 (95% CI: 0.72, 1.45) was found for workers with 5 to 19 years of diesel exposure, and an RR = 1.64 (95% CI: 1.18, 2.29) for those with 20 or more years of exposure, compared with the referent group with 0 to 4 years of diesel exposure.

INDUSTRIAL HYGIENE STUDIES OF RAILROAD WORKERS

Woskie and colleagues (1988a,b) conducted an industrial hygiene survey of U.S. railroad workers in four small northern railroads in the early 1980s to estimate occupational exposures to diesel exhaust. (This study was conducted during a time after the period when the workers in the epidemiologic studies would have been exposed.) They first identified 39 job titles (from among the more than 150 U.S. Interstate Commerce Commission railroad job titles) that encompassed large numbers of workers and that were thought to indicate either minimal or substantial exposure to diesel exhaust. These job titles were then collapsed into 13 job groups and, for some analyses, into 5 career exposure groups (clerks; signal maintainers; engineers and firers; brakers, conductors, and hostlers; and shop workers).

* Pack-years is the number of packs of cigarettes smoked per day times the number of years smoked.

The investigators developed three markers of diesel exhaust exposure: (1) the concentration of respirable-sized particles (RSP); (2) the adjusted respirable particle (ARP) concentration, which removed the particle contribution of environmental tobacco smoke (ETS) from the RSP; and (3) the adjusted extractable mass (AEM) (Hammond et al. 1988).

The RSP was the simplest marker to estimate in over 550 air samples from workers' breathing zones in 13 job groups at the four railroads, as well as in 23 air samples from fixed samplers in various railroad locations. Respirable matter (median aerodynamic diameter ≤ 3.5 µm) was collected on filters for analysis. Investigators also developed a method to collect and analyze nicotine from the same samples as a marker for ETS. The estimated ETS concentration was subtracted from the estimated RSP to obtain the second diesel marker, ARP. Dichloromethane was used to extract the organic chemical components of diesel exhaust, including the mutagens and carcinogens, from the RSP. The fraction of extractable material in the RSP was adjusted for the fraction of extractable ETS for the third index of exposure, AEM. Crump and colleagues (1991) used another index, total extractable material (TEX), which is the concentration of extractable RSP without the ETS fraction removed. None of these measures accounts for other respirable matter in the RSP, such as sand, dirt, or fibers.

The investigators used these data from four railroad yards to estimate a national career mean exposure for ARP (Woskie et al. 1988a,b). They used a linear statistical model to adjust for climate differences and variability of exposures among railroads across the country. This model included weighting factors to estimate the fraction of the year a railroad was in a "cold" (below 10°C) or "warm" (above 10°C) climate (Woskie et al. 1988b).

EXPOSURE-RESPONSE ANALYSES OF RAILROAD WORKERS

The railroad worker cohort study suggested that lung cancer risk increased with increasing cumulative years of exposure (Figure 3). Some quantitative exposure data were available for the industry as well. Because both types of information were available, analysts have used the data to develop exposure-response estimates for diesel emissions and lung cancer.

Crump and colleagues (1991) were the first to develop quantitative estimates of lung cancer risk associated with exposure to diesel exhaust by combining data from the railroad worker cohort study (Garshick et al. 1988) with exposure estimates from the industrial hygiene studies (Hammond et al. 1988; Woskie et al. 1988a,b). Crump and colleagues assigned average exposures as defined in the industrial hygiene studies to members of the railroad worker cohort, on the basis of yearly job codes beginning in 1959. They conducted analyses using RSP, ARP, AEM, and TEX estimates.

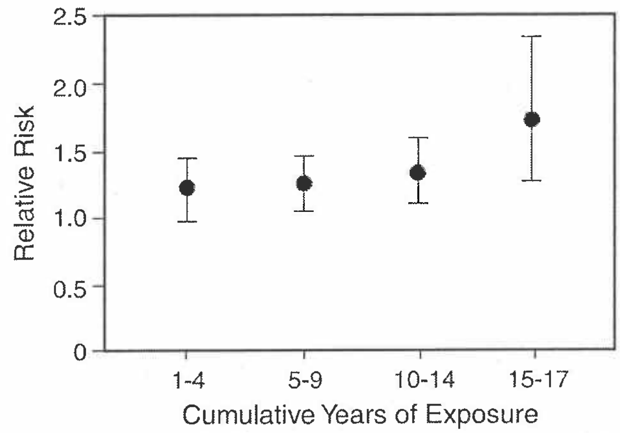

Figure 3. Relative risk of lung cancer by years of exposure to diesel exhaust in the railroad industry through 1980. Relative risk and 95% confidence intervals are shown. (Adapted from Figure 1 in Garshick et al. 1988.)

Crump and colleagues (1991) constructed several different exposure metrics that combined measures of particulate levels with information on regional climates for the U.S.; they used these metrics, plus age, calendar year, and five job categories (clerks; signal maintainers; engineers and firers; brakers, conductors, and hostlers; and shop workers) to conduct more than 50 analyses of the relation between exposure to diesel exhaust and death from lung cancer. All but two analytic models showed that subjects with the highest estimated cumulative exposures had the lowest risk of death from lung cancer (Figure 4).

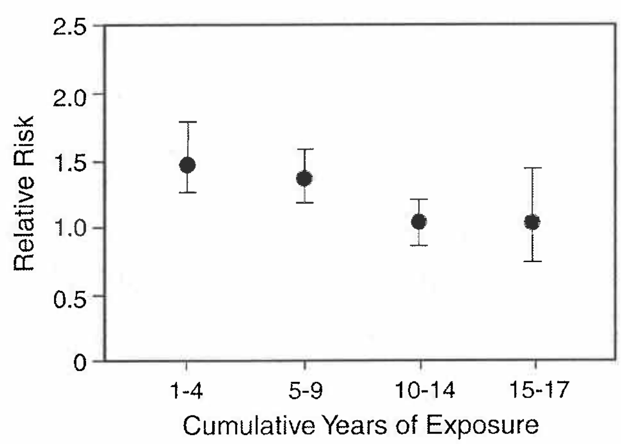

Figure 4. Relative risk of lung cancer by years of exposure to diesel exhaust in the railroad industry, using data from the cohort study. (Adapted from data presented in Crump et al. 1991.)

Crump and associates also discovered a limitation of the original cohort data. Whereas Garshick and colleagues (1988) had compared lung cancer mortality rates between exposed and unexposed railroad workers within the cohort, Crump and colleagues also compared the overall age- and year-specific death rates of the cohort to those rates in the U.S. population (Crump et al. 1991). This comparison suggested that follow-up (that is, determination of vital status) was incomplete between 1976 and 1980 as ascertained by the RRB. Garshick confirmed this, as noted in a letter to the U.S. EPA (Garshick 1991). This underascertainment of deaths from the RRB did not affect the major findings of Garshick and colleagues (1988) because Crump's analyses, limited to the years 1959 through 1976, revealed similar overall excess lung cancer mortality risk (Crump et al. 1991; Garshick 1991). In his letter, Garshick (1991) also presented a new analysis of lung cancer risk by years of diesel exposure, in which the data were modeled to allow the effect of age to vary in the cohort in a time-dependent manner between 1959 and 1980. Although the relative risks for all four exposure groupings were elevated, the estimated effect did not increase with increasing duration of exposure (Figure 5), in contrast to results Garshick had reported previously.

As part of the California EPA's risk assessment of diesel particulate matter, OEHHA analyzed exposure-response relations in the railroad worker data. The five job categories described were combined to form three exposure groups: exposed (engineers and firers; and brakers, conductors, and hostlers; collectively referred to as "train workers"), unexposed (clerks and signalmen), and uncertain (shop workers). Shop workers were excluded from some analyses because their exposure was assessed as uncertain (OEHHA 1998).

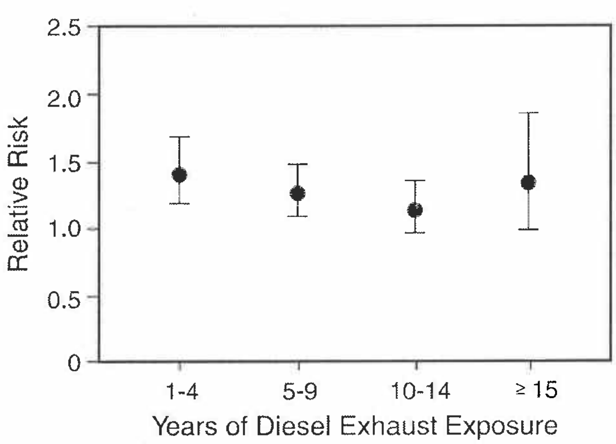

Figure 5. Relative risk of lung cancer by years of employment in the railroad industry through 1976. (Adapted from Table 4 in Garshick 1991.)

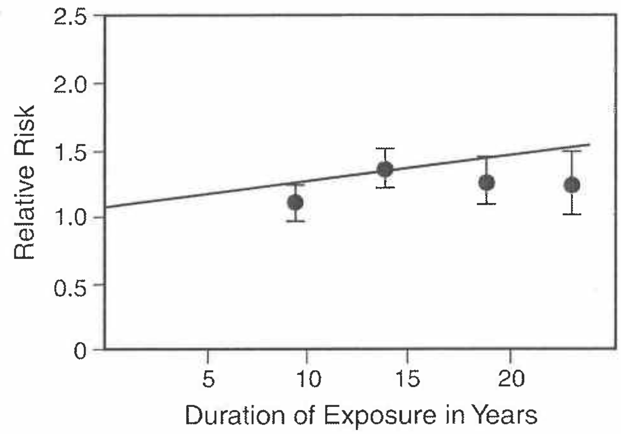

Figure 6. Relative risk of lung cancer by years of exposure to diesel exhaust. (Adapted from Figure 7-2 in OEHHA 1998.)

The analysis by OEHHA (1994, 1998) found a steadily increasing risk of lung cancer with increasing duration of exposure (Figure 6). This result conflicts with the findings of Crump and colleagues (Figure 4) and the revised Garshick analysis (Figure 5). Although the linear regression coefficient is positive, the relation shown in Figure 6 does not appear to be monotonic. On the basis of the linear increase, the California EPA estimated a range of lifetime unit risk (95% upper limit) of lung cancer from exposure to DPM to be from 1.3×10^{-4} (lifetime-µg/m^3)$^{-1}$ to 2.4×10^{-3} (lifetime-µg/m^3)$^{-1}$. The estimated risks are based on several assumptions, including (1) a linear increase in DPM exposure concentrations from zero in 1945 to a peak in 1959 (described below as the "roof" pattern of exposure) that was 1 to 10 times the concentration measured in 1980; (2) a linear decline to the 1980 value after the initial increase and peak in 1959; (3) exclusion of shop workers from some analyses because their degree of exposure was uncertain; (4) various statistical methods to control for age and calendar year; and (5) subtraction of "background" exposure levels measured for clerks and signal maintainers from the exposure levels measured for the train workers.

Different assumptions were made by OEHHA and Crump to reconstruct diesel exposures before 1959, because no actual data were available. Figure 7 shows a schematic representation of how pre-1959 exposure was represented in analytic models by Garshick and colleagues (1988), Crump and coworkers (1991), and OEHHA (1998). The cohort analysis (Garshick et al. 1988) assumed that exposure began in 1959, and that the 1959 exposure level remained constant until 1980 (which has been referred to as the "block" exposure pattern). Crump used the "ramp" exposure pattern, with a linear increase in exposure from the

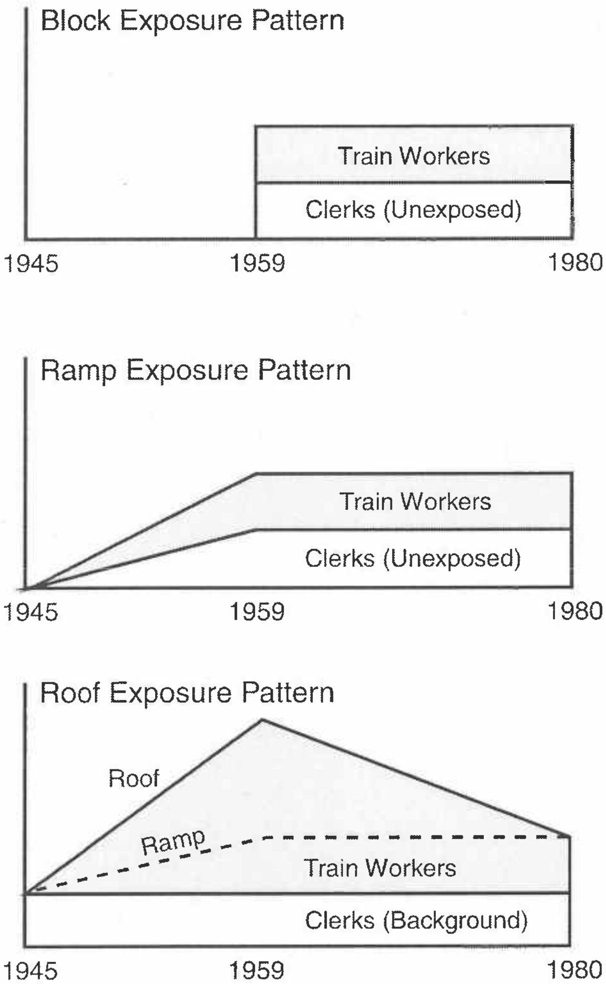

Figure 7. Different exposure patterns from assumptions made about pre-1959 diesel exposures. Garshick and colleagues (1988) made no assumptions about exposure before 1959, which has been referred to as a block pattern. Crump and coworkers (1991) assumed a linear increase in exposure from 1945 to 1959 and constant exposure thereafter (the ramp pattern). The roof pattern (OEHHA 1998) is based on the assumption that engines were "smokier" in the past, increased to a peak in 1959, and decreased to measured levels in 1980. (Adapted from Figure 7-4 in OEHHA 1998.)

time diesel-powered locomotives were introduced in 1945 to a peak of diesel engine use in 1959 and constant exposure levels from 1959 until 1980. This model assumes that exposures for both train workers and clerks followed this pattern, though at different magnitudes of exposure. The "roof" exposure pattern assumes a constant background level of exposure for the clerks before and after 1959. The additional exposure for the train workers was assumed to increase to a maximum in 1959 of three times the exposure level of the ramp model, followed by a decreasing exposure to the levels measured in 1980. Analysts at OEHHA used the roof model of diesel exposure because they thought it more nearly approximated anecdotal reports that engines were "smokier" in the past, and decreased to levels measured in 1980 (OEHHA 1998).

TEAMSTER STUDIES

CASE-CONTROL STUDY

Steenland and colleagues (1990) conducted a case-control study of lung cancer mortality in the Central States Teamsters Union. Cases and controls were selected from among 10,699 male union members who had filed for pension benefits and who died in calendar years 1982 and 1983. Cases ($n = 996$) constituted all deaths in which lung cancer was reported as an underlying or contributing cause of death (ICD code 162 or 163). Control subjects ($n = 1,085$) consisted of every sixth death in the file of decedents, excluding deaths from lung or bladder cancer and motor vehicle accidents. As with the railroad worker case-control study, deaths from nonmalignant respiratory disease were included among the control subjects.

Exposure to diesel exhaust was ascertained in two ways. Interviews with the next of kin were conducted for 82% of cases and 80% of control subjects to obtain a lifetime work history. Study subjects were classified according to the job category in which they had worked the longest: diesel truck driver, gasoline truck driver, driver of both types of trucks, truck mechanic, or dock worker (a person who worked on truck loading docks or in warehouses). Subjects who had never worked in any of the above categories were defined as unexposed to diesel exhaust.

The second source of exposure information consisted of Teamsters Union pension applications that had been completed by the study subjects; these listed each occupation, employer, and the dates of employment. As with the data provided by next of kin, study subjects were categorized according to the job they held the longest: long-haul driver, short-haul or city driver, truck mechanic, or dock worker; others were classified as unexposed. Most subjects had worked in only one job category. The Teamsters Union data did not provide information on whether trucks were gasoline or diesel. The concordance between exposure classifications based on Teamsters Union records and on the next-of-kin interviews was generally high, but it varied among job categories. Over 90% of the men identified by their next of kin as diesel truck drivers were listed as long-haul drivers in the Teamsters Union records, and 82% of workers identified as mechanics by their next of kin were listed as such in the same records. Information on the amount and duration of cigarette smoking was obtained from the next of kin, as was information on asbestos exposure and diet.

When subjects who had ever been employed in any of the index job categories were compared with those who had not, the relative risk of lung cancer was elevated (but not statistically significant) in all major occupational categories except dock workers. Relative risk estimates for lung cancer appeared to increase with duration of employment after 1959 for both long-haul and short-haul truck drivers.

A similar pattern was observed in analyses that were based on length of employment as a driver of diesel trucks, using job histories provided by the next of kin. Employment as a diesel truck driver for 35 years or longer was associated with an 89% increase in lung cancer mortality (RR = 1.89; 95% CI: 1.0, 3.4). However, no relation between duration of employment and excess lung cancer mortality was evident for mechanics working 35 years or more (RR = 1.09; 95% CI: 0.44, 2.7).

INDUSTRIAL HYGIENE STUDY OF TRUCKING INDUSTRY WORKERS

In conjunction with the case-control study of teamsters, Zaebst and colleagues (1991) surveyed exposures to DPM in the four job categories identified by the Teamster Union records: long-haul or road drivers, short-haul or local drivers, mechanics, and dock workers. This survey was conducted in a time period after workers in the epidemiologic study would have been exposed. Samples were measured among workers in these four groups at six "breakbulk" terminals (hubs where inbound long-distance loads are broken into smaller loads for delivery). Additional data were obtained for dock workers at another terminal and for mechanics at a small truck repair shop. In addition, area samples were collected near a highway and in a residential area to estimate background concentrations. Levels of submicrometer-sized elemental carbon (EC_1) particles were used as the principal marker of exposure to whole diesel exhaust. Table 2 presents the EC_1 data from the industrial hygiene study and the odds ratios from the epidemiologic study.

Steenland and colleagues (1992) interpreted the EC_1 measurements as being generally consistent with the epidemiologic results. The industrial hygiene survey (Zaebst et al. 1991) indicated that measured levels of EC_1 for drivers did not differ substantially from highway background levels at the time of the survey.

Different numbers of dock workers were reported by Zaebst and colleagues (1991) and Steenland and colleagues (1998). In 1991, the industrial hygiene study reported that dock workers used equipment with engines powered by diesel (n = 54), gasoline (n = 9), or propane (n = 12). However, primarily propane-powered engines were used by dock workers until diesel-powered engines were introduced in the early 1980s, which is an insufficient latent period for development of lung cancer in 1982 and 1983, when subjects were identified for the epidemiologic

Table 2. Sample Means of EC_1 and Estimates of an Association Between Exposure to EC_1 and Lung Cancer Risk by Job Category in the Trucking Industry[a]

Job Category or Location[b]	n	EC_1 Geometric Mean ± SD[b] (μg/m^3)	EC_1 Arithmetic Mean ± SE[b] (μg/m^3)	Odds Ratio (95% CI)[c]
Dock workers	12	1.3 ± 2.0	1.6 ± 0.4	0.93 (0.55, 1.55)[d]
Mechanics	80	12.1 ± 3.7	26.6 ± 4.1	1.69 (0.92, 3.09)
Short-haul drivers	56	4.0 ± 2.0	5.4 ± 0.9	1.31 (0.81, 2.11)
Long-haul drivers	72	3.8 ± 2.3	5.1 ± 0.4	1.27 (0.83, 1.93)
Roadside area samples	21	2.5 ± 2.4	3.4 ± 0.5	NA
Off-roadway area samples	23	1.1 ± 2.0	1.4 ± 0.2[e]	NA

[b] From Zaebst and coworkers (1991).

[c] From Steenland and associates (1990). Reference job category for odds ratios is workers who had never worked in the other job categories listed nor in any other diesel-exposed job. NA = Not applicable.

[d] Odds ratio from Steenland and associates (1998) for dock workers using propane forklifts only.

[e] Value taken from Zaebst and coworkers (1991); same value appears as geometric mean for off-roadway area samples in Steenland and associates (1998).

study. Subsequent reports utilizing these industrial hygiene data include exposure levels measured only among those 12 dock workers using propane-powered equipment (Steenland et al. 1992, 1998).

EXPOSURE-RESPONSE ANALYSES

Steenland and colleagues (1998) reported results of an exposure-response analysis for EC_1 exposure as a marker for diesel exhaust and lung cancer in the teamster study. In the original case-control study, Steenland and colleagues (1990) had estimated exposures for subjects from work history. Industrial hygiene measures (Zaebst et al. 1991) were combined with past estimates of worker exposure on the basis of the investigators' evaluation of changes over time in both diesel engine emissions and patterns of use in the transportation industry. The estimated exposures from work histories and the industrial hygiene measures were combined with the following assumptions to develop the exposure-response relation.

- Ambient diesel exposure for workers in the trucking industry increased in proportion to the use of diesel engines.
- Past exposures to diesel emissions were estimated using heavy-duty trucks as a marker of diesel engine use and data on vehicle miles traveled (VMT) by heavy-duty trucks from 1949 to 1990.
- Worker exposures were assumed proportional to diesel engine emissions, as estimated from past engine emission levels and changes in emissions over time using existing data on grams emitted per mile traveled.
- The mid-point value of emissions decreased from 4.5 grams per mile in the 1970s to 0.4 grams per mile in the 1990s for new heavy-duty trucks.
- For the subjects in the epidemiologic study, past exposure to EC_1, as a marker for diesel exposure, was estimated by assuming that (1) the average 1990 level could be assigned to all workers in a specific job category; and (2) levels before 1990 were proportional to VMT by heavy-duty trucks and the estimated emission levels of diesel engines.
- Long-haul drivers received some exposure from their own trucks, increasing their estimated exposure by 50% (based on Ziskind et al. 1978).
- Ambient air background levels (1 $\mu g/m^3$/year) were added to the cumulative worker exposure.

Cumulative exposure estimates were calculated for workers by each year of work history and job category. The largest job category was long-haul drivers, and estimates of lung cancer risk were calculated for this group. All analyses were controlled for age, race, smoking, diet, and reported asbestos exposure. Results indicated that a lifetime excess risk of lung cancer death from exposure to 5 $\mu g/m^3$ EC_1 (through age 75) for a male truck driver was 1.6% (95% CI: 0.4, 3.1); that is, an excess of 1.6 deaths from lung cancer for each 100 men. (The excess risk at 1 $\mu g/m^3$ EC_1 is 3×10^{-3}.) The assumptions in the estimate were that emissions in 1970 were 4.5 grams per mile, the worker had 45 years of exposure (from age 20 to 65) at 5 $\mu g/m^3$ EC_1, and there was no lag time when the cumulative exposure was calculated. (Investigators reported that similar findings resulted when a lag was included.) Varying the assumption of level of exposure in 1970 resulted in an estimated range of lifetime risk from 1.4% (95% CI: 0.3, 2.7) to 2.3% (95% CI: 0.5, 4.6). (This range is higher than the unit risk estimate calculated by OEHHA from the railroad worker cohort data.)

Assessment of Railroad Worker and Teamster Studies

When the Panel started to evaluate the epidemiologic studies of diesel-exposed workers, one challenge was understanding why the exposure-response association from various analyses of the railroad worker cohort data produced apparently conflicting results. Another was whether and how to address the exposure-response analysis of the teamster data (Steenland et al. 1998), which was published after the Panel's work was under way, and had not been subjected to the same level of scrutiny as the railroad worker studies. The Panel concluded that both sets of studies should be systematically reviewed to weigh their strengths and limitations for QRA.

In general, the results of both sets of studies are consistent with findings of a weak association between death from lung cancer and occupational exposure to diesel exhaust. Although the secondary exposure-response analyses of the railroad worker cohort data are conflicting, the overall risk of lung cancer was elevated among diesel-exposed workers.

In addition to the availability of some associated exposure data, several strengths are evident in these railroad worker and teamster studies. Both included large numbers of subjects (55,407 employees with 1,694 lung cancers comprised the railroad worker cohort, and 1,256 lung cancers were the basis for the case-control study; the teamster case-control study was based on 996 lung cancers) from industries in which some occupations entailed exposure to diesel exhaust. Job categories with known exposure to asbestos were either excluded or controlled for in the analyses. Both of the case-control studies adjusted for cigarette smoking as a confounding variable in analyses of the relation between diesel exposure and lung cancer mortality.

The Panel addressed the questions posed in its framework (see Table 1 in the Background chapter and Appendix B) for evaluating the railroad worker and teamster studies. Because the questions represent an ideal study, the Panel did not expect a strict "yes or no" response to each question. Instead, the systematic evaluation of these studies within this framework was intended to inform the process for others who may want to understand or use these data, and to provide a means to weigh study strengths and limitations. This systematic approach also was intended to sharpen the focus on where limitations from previous work might help define research needs.

RAILROAD WORKER STUDIES

DESIGN

1. **Was the study design efficient, and did it specifically consider power, potential types of bias, and latency?**

A cohort study (Garshick et al. 1988) and a case-control study (Garshick et al. 1987) reported findings on railroad workers. The authors did not report how power calculations were conducted or whether factors other than overall association between diesel exposure and lung cancer were considered. For weak associations, even large studies may not be powerful enough to detect associations, particularly in subanalyses.

A cohort study design, as used by Garshick and colleagues (1988), is appropriate for enumerating the workers to be followed for development of disease. A case-control study design requires additional assumptions for use in QRA; when the case-control study is not nested in a cohort design (as it was not in Garshick et al. 1987), still more assumptions are required, which can limit the conclusions to be drawn. For example, it is possible that the deaths in the case-control study did not include all lung cancer deaths that occurred in the population eligible for RRB death benefits, because both cases and controls were deaths identified between March 1, 1981, and February 28, 1982, which was after the period when follow-up was considered complete in the cohort study as reported by Crump and colleagues (1991).

A case-control study may be less suitable than a cohort study for QRA; if the control causes of death used are related to smoking or to other risk factors for lung cancer, including the exposure of interest, this may lead to biased results. Control deaths (Garshick et al. 1987) were primarily from cardiovascular disease (CVD), which is also associated with cigarette smoking. If risk of CVD differed among job categories (that is, by exposure), and within category of smoking status, a selection bias may have been introduced. The authors did not discuss such a possibility in their published report. A case-control study nested in the cohort study would be a preferable study design because it avoids such bias.

In the cohort study, subjects were followed for up to 21 years. This may have limited the power of the study by providing too short a latency period for the manifestation of lung cancer, given that the latency period from exposure to a substance until the development of solid tumors is often 20 to 40 years (although some can appear in 10 years or less).

2. Were adequate quantitative exposure and covariate data planned and collected?

Both railroad worker studies were retrospective studies conducted on the basis of death certificates, which obviously precluded interviewing subjects to obtain exposure data. However, an industrial hygiene survey of the railroad industry was conducted to measure RSP adjusted to remove the ETS fraction, as a marker for DPM (Woskie et al. 1988a). This survey was conducted at a nonrandom sample of four small railroads, and measurements were in a time period after the cohort members were exposed. The diesel-exposed or unexposed job categories in the epidemiologic studies, which had been designated on the basis of job title and duties, were confirmed with the industrial hygiene samples of railroad jobs (Woskie et al. 1988a,b). (For a more detailed discussion of exposure issues, see the Exposure Assessment section.)

3. Was the literature reviewed for relevant study methods and previous research findings?

The literature review in the main report of the cohort study did not include references related to QRA. Such references would not be expected, however, because a QRA was not originally intended.

4. Were plans made for postpublication data scrutiny?

The Panel did not know whether the researchers originally intended to share their data. The investigators did, however, generously share data with the U.S. EPA (and, through the EPA, with Dr. Crump). In turn, Dr. Crump shared the data with Dr. Dawson in the OEHHA (California EPA). Most recently, all of these individuals have shared data with the HEI Panel. This was extremely valuable in understanding the complexities inherent in this data set, and the Panel greatly appreciated all of their cooperation.

EXPOSURE ASSESSMENT

1. Were detailed lifetime histories of occupational exposures collected?

All members of the cohort were active railroad workers in 1959 and had at least 10 years' history of employment; investigators reported that no information on work histories was available for the years before 1959 (Garshick et al. 1988). This lack of data on exposures before 1959 adds to the uncertainty in quantitative risk estimates developed from studying this cohort. The researchers chose 1959 as the starting date because approximately 95% of railroad locomotives were diesel-powered (as opposed to steam-powered) by that time, according to a U.S. Department of Labor report (1972). Duration of employment since 1959 was used to represent the duration of exposure to diesel exhaust after 1959. Although the investigators had neither a detailed occupational history nor a history of exposure, they verified that more than 90% of workers who were between 40 and 44 years of age in 1959 remained, over their careers, in job categories with the same exposure classification. Garshick and colleagues (1988) accounted for exposure history in "diesel-years," that is, the total number of years in a diesel-exposed job category from 1959 until death or retirement.

2. Were known chemical and physical characteristics of the main exposure specified?

In the original cohort study, the main exposure of the railroad workers was considered to be "diesel exhaust," which is a complex mix of many compounds in both particle and gas phases. Little historical information was available on the chemical and physical nature of the diesel emissions from locomotives, or on how the emissions might have varied by railroad or job category over the time period covered in the cohort study. The industrial hygiene study, conducted between 1981 and 1983, focused on RSP as a marker for exposure to diesel exhaust, but diesel exhaust is only one of many sources of ambient particulate matter. The contribution of ETS, a major source of indoor particles, to the total particulate samples was adjusted for by a correction factor derived from measured particle-phase nicotine (Hammond et al. 1988). Levels of NO_2, a constituent of diesel exhaust, were examined at the four studied railroads across seasons, but this measurement was not useful for distinguishing among the job categories (Woskie et al. 1989).

3. Were potentially confounding exposures measured or estimated?

In the railroad worker studies, sources of exposure to respirable particulate matter in addition to diesel exhaust were likely to include outdoor nondiesel pollution, personal activities (e.g., smoking), indoor residential exposures (e.g., ETS or residential coal heating), and other occupational exposures (e.g., asbestos). These exposures, if related to both diesel exposure and lung cancer, could be considered possible confounders. That all of these exposures were confounding variables is unlikely.

Asbestos, however, is a potentially confounding exposure among railroad workers. The railroad worker cohort study excluded workers in job categories known to be "asbestos-exposed," and analyses were conducted both with and without the inclusion of job categories in which asbestos exposure was suspected. The case-control study controlled for asbestos exposure in the statistical analysis (Garshick et al. 1987). The possibility of confounding by other exposures before 1959 could not be completely evaluated.

Retrospective mortality studies have limited ability to obtain good data on risk factors such as smoking or lifestyle variables, which often must be obtained from next of kin. The case-control study included smoking data from next of kin; the investigators reported that when results were adjusted for smoking, they did not differ substantially from unadjusted results. Thus, it is likely that results were not seriously confounded by smoking. However, because smoking is strongly associated with lung cancer in most studies, and because the reported association between diesel emissions and lung cancer is weak, smoking needs to be controlled precisely in analyses of the effects of exposure to diesel exhaust. Even if smoking is not shown to be a confounder in a particular study, when a weak association between a risk factor and lung cancer is under investigation, the validity of any findings is likely to be questioned if the analysis did not control for smoking. In addition, smoking may modify the risk of exposure to diesel exhaust, and this modification can be investigated only if smoking data are available.

In the industrial hygiene study by Hammond and colleagues (1988), the ARP removed the ETS contribution. The adjusted marker (ARP) is an improvement over a crude classification of each job as either exposed or unexposed to diesel exhaust with no consideration of either smoking or ETS. When the ETS estimate was subtracted from the RSP concentration, ranking of the diesel-exposed job categories changed from that based on RSP alone.

Woskie and colleagues (1988b) developed a model for estimating mean levels of DPM exposure in national career groups. Although this model included data on ARP concentrations, railroad job category, and climate, it did not consider the impact of outdoor nondiesel particulate matter on estimates of exposure to DPM; instead, one estimate of the contribution of outdoor particulate levels was applied to all workers regardless of location or time. This procedure is questionable, however, because outdoor particulate mass concentrations show considerable geographic variability across the U.S., and over time; substantial reductions have been noted in measured levels. For example, the trend in particle emissions data indicates a threefold reduction in emissions between 1940 and 1982 (National Air Pollutant Emissions Trends 1997), a time that overlaps the period during which the railroad worker cohort was exposed. Considering background outdoor particulate levels over space and time, and by railroad, might substantially alter estimates of total particle exposures, and hence alter estimates of the health effects of diesel exhaust.

4. Were magnitude, duration, and variability of exposure determined?

Exposure data were collected by Woskie and colleagues (1988a,b) several years after the workers in the epidemiologic studies were exposed. The 13 job codes from the industrial hygiene studies were combined to develop the 5 career groups as shown in Table 3. (Arithmetic means are presented rather than geometric means, because comparable data were available in this form for each of the exposure estimates.) The authors discussed some concerns they had about the exposure data used in the model to estimate the national career group mean exposures (Table 3, last column). Particle mass measurements varied considerably among the job groups for both corrected (ARP) and uncorrected (RSP) concentrations. The uncertainty associated with the final grouping of occupations into these job categories should be considered when the exposures for each group are discussed.

Table 3 indicates that several job exposure groupings are possible, with all such groupings having an undefined but large uncertainty. For example, clerks (who are considered "unexposed") appear to have RSP exposures (RSP = 125) similar to those (RSP = 126) of freight conductors (who are considered "exposed"). Engineers and firers, and brakers and conductors are combined as "exposed"; however, their RSP estimates range from 75 (passenger engineers and firers) to 231 (hostlers). When ARP values are considered, clerks (ARP = 42) and signal maintainers (ARP = 58) appear to have more similarly low exposures than when RSP is used. However, passenger engineers and firers (ARP = 51), yard engineers and firers (ARP = 69),

Table 3. Railroad Worker Exposure Assessment Data[a]

Career Group	Job Group	Number of Workers Monitored[b]	Number of Samples Used for ETS Estimates[c]	Particle Concentration as Arithmetic Mean: RSP[d] (± SD)	ETS[e]	ARP[f] (± SD)	AEM[g]	Modeled National Career Group[h] Mean ± SD (μg/m³)
Clerks	Clerks	59	36	125 ± 75	88	42 ± 36	7	33 ± 1
Signal maintainers	Signal maintainers	13	14[i]	69 ± 39	10	58 ± 33	23	58 ± 4
Engineers and firers	Freight	55	37	115 ± 67	18	94 ± 55	30	71 ± 3
	Yard	50	20	108 ± 109	44	69 ± 70	24	
	Passenger	23	21	75 ± 52	23	51 ± 35	16	
Brakers and conductors	Freight conductors	62	48	126 ± 65	52	69 ± 52	30	89 ± 3
	Freight brakers	21	16	145 ± 80	36	102 ± 62	8	
	Passenger	35	33	111 ± 62	6	104 ± 58	27	
	Yard	32	7	180 ± 117	75	114 ± 76	17	
	Hostlers	8	8	231 ± 134	7	224 ± 130	33	
Shop workers	Electricians	42	16 (Summer)	256 ± 332	37	192 ± 248	37	141 ± 8
	Machinists	110	32 (Summer)	191 ± 146	29	147 ± 120	55	
	Supervisors and other shop workers	24	12	244 ± 141	30	155 ± 83	43

[b] Number of workers monitored over one work shift with a personal monitor for particle mass (Woskie et al. 1988a).

[c] From Hammond and associates (1988).

[d] RSP = concentration (μg/m³) of respirable particle mass (≤ 3.5 μm) measured by personal monitors for four railroads (Woskie et al. 1988a).

[e] ETS = respirable particle mass concentration (μg/m³) associated with ETS (Hammond et al. 1988), determined from the analysis of composite personal monitoring particle mass samples by job group and railroad for three railroads.

[f] ARP (in μg/m³) = (RSP − ETS)/volume of air sampled (Woskie et al. 1988a).

[g] AEM (in μg/m³) = [(μg RSP × fraction extractable) − (μg ETS × fraction ETS extractable)]/volume of air sampled (Hammond et al. 1988).

[h] Modeled national career group exposure determined from model that incorporates ARP concentrations, national railroad worker job data, and climate data in a linear model (Woskie et al. 1988b).

[i] Numbers as reported.

and freight conductors (ARP = 69) also appear to have low-level exposures, although for analysis they are considered "exposed" along with those who are listed with much higher ARP levels. Such misclassification as to which jobs are considered "exposed" or "unexposed" could bias study results.

The variability in job exposure estimates may be the result of several assumptions that were made in the industrial hygiene study. First, the selection of a 10°C cut point to represent climate effects on DPM exposures is arbitrary and not well supported. Second, repeated personal monitoring on a subpopulation of workers in different job groups would have been preferable to a single measurement for estimating measurement error and day-to-day variability. Variability associated with these sources may add considerable uncertainty to estimated job group exposures. Concentrations of RSP in various job groups might have changed substantially over time in ways that could be related to newer engine technology, changes in ventilation, differences in diesel maintenance practices, or other variables not examined. The model of career exposure means (last column of Table 3) would have been more informative for use in QRA if the model had considered various scenarios of time-varying concentrations.

5. Were industrial hygiene data and historical data on use and repair of machinery and equipment obtained?

Although Woskie and colleagues (1988b) obtained some information on national dieselization of the railroad industry, actual exposure measurements were made at four small railroads that were unlikely to represent the national diversity of equipment and exposures. Detailed historical exposure conditions in the railroad shops were evaluated in terms of NO_2 levels, historical records of use and changes in ventilation systems, and a comparison of records of historical locomotive use with locomotives in use at the time of the industrial hygiene study. Detailed historical information on the purchase and maintenance of diesel locomotives, fuel use, and repair shop design, helpful to the historical reconstruction of exposures, was not available. Such additional information might better define historical exposure trends by railroad.

6. Were personal exposure measurements obtained, and were they representative of the population studied?

The industrial hygiene exposure assessment provided information that identified categories of railroad workers who might be at risk of exposure to diesel particulate emissions from locomotives. As noted, however, the results in Table 3 indicate that other groupings of diesel-exposed jobs are possible, which introduces additional uncertainty in the exposure data for use in QRA.

The exposure assessment conducted by Woskie and colleagues (1988a,b) probably does not represent personal exposures of railroad workers to diesel exhaust in either space or time, and raises several issues. First, the four small railroads sampled by Woskie and colleagues are in the northern U.S. and are not necessarily representative of the national average railroad exposure, during either the period of sampling (1981–1983) or the period of exposure covered by the epidemiologic studies (1959–1980). Second, a convenience sample of 530 workers from 39 job codes was selected for personal monitoring of particle mass during a single work shift, which may not accurately represent exposures of all workers in those job codes. Third, corrections to particle mass exposures were determined from composites of personal samples within job group at each railroad (Hammond et al. 1988). Data on ETS were available from only three of the four railroads. Although the composite samples were necessary to have a sufficient mass of particulate matter for marker analysis, the few resulting observations did not allow assessment of the variability of the contribution of ETS and inorganic mass (e.g., sand, dirt, fibers) to the measured personal diesel exposures either by job group or by railroad. A statistically drawn random (e.g., stratified random) sample from railroads across the country would have provided greater confidence in the representativeness of the data.

7. Were uncertainties in exposure assessment quantified?

When Woskie and colleagues (1988a) developed their exposure intensity estimates for various job categories, it was not with the intention that the estimates would be used for QRA. Woskie and colleagues provided estimates of error resulting from sampling variation but did not quantify uncertainties from all sources, as would be desirable for results intended for use in QRA. Sources of uncertainty include (1) extrapolation of data from four railroads to the entire U.S., (2) use of results from 1980 to estimate earlier exposures, (3) lack of exposure histories prior to 1959, (4) failure to account for seasonal variations in exposures, (5) problems in selecting the appropriate job category groupings, and (6) use of respirable particulate matter as a surrogate measure of DPM. Analysts who have made use of the Woskie and colleagues data (Crump et al. 1991; OEHHA 1998) also have not quantified uncertainties from all sources, although these analysts discussed problems with the exposure measurements.

OUTCOMES

1. Were outcomes defined in specific and objective terms?

Death certified as primary lung cancer was defined as the outcome for the railroad worker case-control study (Garshick et al. 1987). In the cohort study (Garshick et al. 1988), the outcome included lung cancers mentioned either as the underlying cause of death or elsewhere on the death certificates. Lung cancers identified on death certificates can include false positive identification of disease, especially if a cancer is metastatic rather than primary in the lung, in addition to false negatives from certification of deaths to some other disease when lung cancer is the cause. That is, death certificates are likely to overestimate the number of lung cancer deaths by including metastatic sites. The best identification of lung cancer for incident cases would be by pathologic examination of a tissue specimen; however, this process is more expensive than a death certificate review. If some cancers metastatic to the lung were differentially misclassified as primary cancers, the impact on risk estimates used in QRA could be in either direction.

2. Was the full range of outcomes included in cohort studies?

Garshick and colleagues (1988) reported only lung cancer in their cohort study, whereas Crump (1999) has looked at other mortality outcomes in association with exposure to diesel exhaust, including heart disease and stroke. These findings have shown decreased risk for overall mortality, as well as for cause-specific mortality, with longer duration of employment.

3. Were participants actively followed to determine outcome status and the date outcome occurred?

Crump and colleagues (1991) compared all-cause mortality in the railroad cohort with U.S. mortality rates, and showed that follow-up was incomplete after 1976. They found that although age-specific death rates in the cohort (overall job categories) remained fairly constant through 1976 (consistent with the U.S. pattern in this period), after 1976 death rates for the cohort dropped (Crump et al. 1991). Garshick reexamined the data and verified that mortality follow-up after 1976, as determined by the RRB, was incomplete (1991). In the cohort study, mortality was determined using the records of the RRB benefits plan. This appears to have been an incomplete method of mortality follow-up, and whether the incomplete follow-up is nondifferential by job category is unknown.

ANALYSIS

1. Were analytic methods specified a priori?

The original investigators were clear that they would use job category and employment duration to estimate exposures to diesel exhaust among job categories without attempting to make quantitative estimates. Although the Panel did not have the original protocol for this study, no evidence would indicate that the approach used was influenced by the hypothesized relation between potential exposure measures and risk of death from lung cancer. Crump and colleagues (1991) used quantitative data to distinguish among job categories and considered many different measures of exposure, all of which led to a similar conclusion; that is, the risk of lung cancer decreased with longer duration of employment. The OEHHA (1998) based most of its analyses of the cohort data on a metric of duration of employment and on the difference between train workers and clerks; however, it considered a variety of assumptions regarding increasing diesel exposure until 1959 and its gradual decrease afterward.

2. Was the appropriateness of the statistical approach demonstrated, and were potential biases explored?

The published models for the cohort and case-control studies did not report any validation procedures. Of possible concern in these models is that age in 1959 was treated as a continuous variable*, and no term was included for interaction with calendar year, which would have adjusted for attained age† and calendar year. Other analysts of the railroad worker data have used different approaches for adjusting for age and calendar year.

The OEHHA did not account for variations in risk by job category, and none of the analysts fully investigated the possibility that time patterns of lung cancer development might differ for various subgroups. The investigators did not publish a description of how *p* values and confidence intervals were calculated.

3. Were exposure-response relations statistically explored?

The conflicting results obtained by secondary analyses of the railroad worker data are central to the issue of whether these data should be used in a QRA of diesel exhaust. Although the railroad worker data have been used for QRA, Garshick (1998) has not supported this use.

The model used for the original railroad data analysis (Garshick et al. 1988) was limited, and neither goodness of fit nor attempts to quantify the risk as a function of exposure were explored. The analysis included a comparison of estimates by age in 1959, and interpreted the larger risks for the younger age groups as reflecting larger cumulative exposures for the younger subjects rather than as effect modification.

Results in the railroad worker study have been analyzed with either no lag time to allow for latency or induction of cancer, or with a five-year lag. The five-year lag was used by secondary analysts (Crump et al. 1991; OEHHA 1998; Crump 1999).

In the original analysis of the cohort railroad data (Garshick et al. 1988), exploration of alternative models was limited to an analysis considering a lag period and an analysis that excluded shop workers and hostlers who

* When age is treated as a continuous variable, the actual age of the subject is included in the analysis. If age is considered as a categorical variable, ages of the subjects are divided into either 5- or 10-year groups, for example, and a variable representing the age group is included in the analysis rather than the actual age.

† Attained age is the age at risk for a particular calendar period and would include everyone in the cohort who is at risk.

may have been exposed to asbestos. The OEHHA explored ramp and roof patterns of pre-1959 exposures, as well as several approaches for adjusting for age and calendar year period. Crump's original work (Crump et al. 1991) explored different models for adjusting for the effects of age, calendar year, and exposure groups.

In the analysis of the railroad worker cohort study (Garshick et al. 1988), with all job categories combined, relative risks appeared to increase with years of exposure to diesel exhaust (see Figure 3 in the chapter Summary of Railroad Worker and Teamster Studies); exposure in the year of death and the preceding four years was disregarded. This finding was important because it supported an exposure-response effect and stimulated interest in using these data for QRA.

The Panel has conducted its own limited analysis of the railroad worker data. The objectives of these analyses were specifically to assist the Panel in its task of verifying and better understanding previous analyses, and to clarify reasons for differences between the results obtained by Crump (see Figure 4; a negative exposure-response relation) and by OEHHA (see Figure 6; a positive exposure-response relation). The Panel's analyses were limited to these objectives only, and were not intended to be a complete exploration and evaluation of the railroad worker data or to provide a model for QRA. A detailed explanation of the Panel's methods of analysis, assumptions, and results is presented in Appendix C. The Panel also recognizes that its own analyses are subject to the same outside scrutiny as others' have received.

The Panel's data exploration indicates that overall, lung cancer risks for train workers, within each duration of employment group, were higher than those for clerks and signalmen; shop workers had intermediate risks (Figure 8). However, within the exposed groups (train workers and shop workers), lung cancer risk decreased with increasing duration of employment. Simple measures of exposure, determined by multiplying duration of employment by exposure intensities assumed to be constant for the clerks/signalmen and train worker groups, were also analyzed. With no adjustment for job category, a positive slope was obtained, which was statistically significant when zero intensity was assumed for the clerks and signalmen group. To clarify the extent to which this positive response was due to the difference in baseline risks for train workers compared with clerks and signalmen, the variable *GRP* to measure this difference was included in the model. When this was done, the direction of association with exposure became negative; this result reflects entirely the decreasing association with increasing employment duration for train workers, and demonstrates that the positive

Figure 8. Panel's analysis depicting consistently elevated risk of lung cancer for train workers compared with clerks for each time period, but decreasing risk by job category over duration of employment. See Appendix C for details.

exposure-response relation obtained, without adjusting for *GRP*, was entirely due to the baseline differences between the two job categories.

These patterns are not consistent with a monotonically increasing association between cumulative exposure to diesel exhaust and lung cancer risk. If risk increased consistently with increasing exposure, a positive trend with duration of employment would be expected for the exposed groups (including train workers), even if exposure magnitudes were incorrect (see Appendix C).

The Panel's analytic model that was similar to the model that served as the basis for the California OEHHA risk assessment did not fit the data; a strong improvement was seen in the fit of the model with the addition of a variable reflecting the difference between train workers and clerks/signalmen. Although some definitions of exposure used by the Panel and by the OEHHA were different, it seems unlikely that these differences affected the Panel's qualitative conclusions.

The Panel's conclusions regarding the railroad worker data analyses did not depend either on method of adjusting for age and calendar time or on the assumption about exposure patterns before 1959.

Crump and colleagues (1991) and Crump (1999) have reported various analyses of the railroad worker data, and have investigated duration of exposure since 1959 as well as more complex measures of exposure than those cited here. However, all results are likely to reflect the negative association of risk with increased duration of employment within job category groups. Crump (1999) has noted that the OEHHA positive slope is driven by the difference in risk between train workers and clerks, and the Panel's analyses confirm this. By showing results of analyses with and without adjustment for job category (intended to indicate exposure intensity), the Panel has attempted to clarify the roles of job category and duration of employment in the differences in results obtained by the OEHHA (1998) and by Crump and colleagues (1991, 1999). An expanded discussion of the Panel's analyses is in Appendix C.

4. Were uncertainties in risk estimates quantified, especially those resulting from exposure measurement error?

All analysts of the railroad worker data have evaluated statistical uncertainties, although the assumptions underlying the normal approximations were not validated. Uncertainties in the risk estimates resulting from exposure measurement error were not explored by any of the analysts. However, this was not relevant for the cohort study (Garshick et al. 1988), because that study did not use quantitative measures of exposure. Crump and colleagues (1991) did not specifically address the issue of measurement error, but presented results on the basis of several definitions of cumulative exposure and examined the effect of excluding shop workers from the analyses. They also commented on the uncertainties in exposure estimates and the possibility that these uncertainties could mask or distort diesel-related effects. The OEHHA (1998) listed uncertainties in the mathematical aspects of modeling, and used several simple models to explore some of the variability due to uncertainty (see Appendix F of its report).

DISCUSSION OF USING RAILROAD WORKER DATA FOR QUANTITATIVE RISK ASSESSMENT

The original railroad worker studies (Garshick et al. 1987, 1988) reported an elevated overall risk of lung cancer with increasing years of exposure to diesel exhaust, when all job categories were combined; however, when the Panel analyzed the cohort data by duration of employment for each job category, a negative association was seen in each group. That is, among train workers, and to a lesser extent among shop workers, the relative risk of lung cancer does not appear to increase with longer duration of employment (Appendix C).

A negative exposure-response relation might be present in these data for several possible reasons: several types of bias could affect the data, alone or in combination, in such a way as to mask a true positive association. For example, results could be affected by unmeasured confounding variables, such as cigarette smoking, previous occupational exposures, or other sources of pollution, that might be associated with diesel exposure as well as lung cancer. As noted previously, smoking, which is strongly associated with lung cancer risk, could not be assessed directly in the cohort study (Garshick et al. 1988), and estimates of lung cancer risk from the case-control study might have been biased.

Exposure misclassification is another possible source of bias in these data, especially because a dichotomous assignment of diesel exposure ("yes" or "no" by job categories) is a crude method for determining exposure. Also, the year when workers were first exposed to diesel is unknown. If dieselization was 50% complete in the early 1950s, some workers in a job category could actually have more "exposure duration" than others in the same category, thus diluting a possible association among those exposed the longest. Dosemeci and Stewart (1996) have demonstrated the impact of misclassification in exposure categories on estimates of relative risks. If misclassification is random (that is, there is no overall tendency for over- or underestimation of exposure), estimated risks are likely to be lower than their "true" values. Their findings show that the magnitude of bias depends strongly on the proportion of misclassified subjects. Job categories of exposure overlap (Table 3) and such a multidirectional misclassification of exposure of an unknown proportion of workers seems likely.

Still another possible reason for the negative association might be the use of "duration of employment" as a measure of exposure. Calendar time and duration of employment are highly correlated, and separating out the effect of duration of employment could be difficult. Doll (1985) has reported examples of nonmonotonic increases in cancer risk with longer durations of employment in an occupationally exposed job, and indicates that using this variable alone could lead to findings requiring cautious interpretation.

One more possible source of bias in these data is the "healthy worker survivor effect" (Arrighi and Hertz-Picciotto 1994). That is, workers who are "healthier" and less susceptible to disease might stay in the work place longer, so that those employed for longer periods might show a smaller elevation in risk than those employed for a shorter duration.

Bias also could be introduced if lung cancer deaths were differentially or incompletely ascertained. If lung cancer were more likely to be underascertained among those employed longest in diesel-exposed jobs, the result would be a lower risk with longer duration of employment. However, such differential ascertainment seems unlikely.

The preceding critique emphasizes the challenges involved in correctly analyzing and interpreting these railroad worker data. The Panel's opinion is that discussion of the uncertainties in these data should accompany any presentation of a quantitative risk estimate. However, despite the reason or reasons why the relative risks in these data decrease with duration of employment, the lack of a positive exposure-response association in the railroad worker cohort data substantially weakens that study's potential to provide a reliable quantitative estimate of risk of exposure to diesel engine emissions.

TEAMSTER STUDIES

As indicated, the teamster exposure-response analysis (Steenland et al. 1998) was published only after the Panel started working; therefore, the evaluation of this set of studies is less extensive than for the railroad worker studies. Also, the Panel did not request data from these investigators, thus its assessment was made on the basis of the published reports only.

DESIGN

1. Was the study design efficient, and did it specifically consider power, potential types of bias, and latency?

The teamster case-control study identified cases and controls from among members of the Teamsters Union who filed for pension benefits after at least 20 years in the Union, and who died in 1982 and 1983. The cases were deaths from lung cancer, and the published study (Steenland et al. 1990) did not indicate the distribution of causes of death for the controls. It is likely that, as in the railroad study, control causes of death were largely related to CVD. If this is the case, some control causes of death may have been related to diesel exposure, smoking, or both. Bias resulting from control subjects used would affect the estimate of risk and any QRA based on the study results.

In the teamster study, mechanic was the job category with the highest assigned diesel exposure; intermediate were long-haul and short-haul truck drivers; dock workers were assigned low exposure; and the unexposed category was composed primarily of dairy workers. It is not known whether the risk of dying from any of the control causes of death differed among the job categories or within strata of cigarette smoking, because of differences in diet, physical activity on the job, or other factors. If the risk differed, study findings could be biased.

Workers had to have 20 years of tenure in the industry to be eligible to apply for pension benefits, and data analyses included models with either 1960 or 1965 as the start of a worker's exposure to diesel exhaust. Deaths were ascertained between 1982 and 1983. If the development of lung cancers has a latency period of 20 years, it is likely that only the minimum time period passed for the development of the tumors, because the latent period can be as long as 40 years.

2. Were adequate quantitative exposure and covariate data planned and collected?

Next of kin provided data on smoking, diet, work history, and asbestos exposure for cases and controls. The investigators used these data to evaluate and control for possible confounding effects of these exposures on the association between diesel exhaust exposure and lung cancer. Work history data also were included in the pension applications available in the Teamsters Union records.

An industrial hygiene survey (Zaebst et al. 1991) measured EC_1 as a marker for diesel exhaust. The samples were taken in a time period after cases and controls would have been exposed, and might not represent actual exposures in space and time. However, the estimated exposures of teamsters to diesel exhaust are of greater relevance to public health than those of the railroad workers, because the teamster exposures are closer to the range of ambient levels of diesel emissions.

3. Was the literature reviewed for relevant study methods and previous research findings?

The literature reviews in the teamster studies are partial and brief. Because the original case-control study was not designated for QRA, a review of relevant methods would not be expected.

4. Were plans made for postpublication data scrutiny?

Planning for postpublication data scrutiny generally is not a major consideration of researchers. However, understanding of the railroad worker data has improved with each additional review. If the teamster data also are reassessed by the original investigators and other analysts, this is likely to yield additional insights and understanding. The exposure-response findings are still "young" in the literature and can benefit from critical peer review, examination by other researchers, and further exploration of possible biases.

EXPOSURE ASSESSMENT

1. Were detailed lifetime histories of occupational exposures collected?

Work histories were obtained for cases and controls from two sources, next-of-kin interviews and teamster pension applications. Next-of-kin interviews, administered by phone (20%) and mail (80%) to spouses (76%)

and others (24%), included information on work histories and several potential confounders, including smoking, diet, and asbestos exposure. Workers were classified into the job (exposure) category in which they had worked the longest. The categories were truck driver (diesel, gasoline, or both), diesel truck mechanic, and dock worker. The uncertainties associated with using questionnaire data and the impact of those uncertainties were not assessed. Although most pension applications reported that the worker had worked primarily in one job category, the impact of changes among job categories was not explored.

Work histories in the teamster pension applications, including all teamster jobs, were self-reported. These were also reviewed and used to assign workers into job (exposure) categories, although records did not differentiate between diesel and gasoline truck engines. Again, workers were assigned to the category in which they were employed the longest. The Teamsters Union assigned a U.S. census code for occupation and industry for each job a man included in his pension application. The four main occupations, based on records, were long-haul drivers, short-haul or city drivers, truck mechanics, and dock workers. The uncertainties associated with the exposure categories derived from the teamster records, and from combining the information from both the teamster records and the interviews, were not explored.

2. Were known chemical and physical characteristics of the main exposure specified?

The case-control study did not include estimates of exposure, but a companion industrial hygiene study was conducted after the epidemiologic study period ended. Steenland and colleagues (1992) derived job-specific exposure estimates from industrial hygiene measurements of EC_1 made by Zaebst and colleagues (1991). EC_1 is a reasonable marker for DPM, at least in terms of establishing relative exposures. It is more specific to diesel exhaust than RSP and relatively free of interference from ETS, an important particle source. On the basis of EC_1 measurements, Zaebst and colleagues (1991) provided some useful insights into the nature of diesel exposure for teamsters.

Relating EC_1 to DPM can be complicated, because the EC_1 fraction of DPM is variable and has probably increased over the period of exposure (Sawyer and Johnson 1995). This matter needs to be explored further if a quantitative risk is assigned. A carcinogenic fraction in DPM has not been identified, and there is no assurance that the proportion between that fraction and DPM or EC_1 has been constant. However, EC_1 is probably the best marker for DPM available at this time.

Nondiesel sources of elemental carbon and their ambient concentrations have changed over time, and geographic differences in concentration probably exist as well. Other sources of elemental carbon include gasoline engines, tire and brake wear, stationary combustion sources, and industrial processes; nondiesel sources were not considered in the assessment by Steenland and colleagues (1998). Although elemental carbon from stationary sources may have decreased over time, a recent study reports a substantial elemental carbon contribution from gasoline engine emissions that should be further considered (Northern Front Range Air Quality Study [NFRAQS] 1998) in the retrospective assignment of exposures by use of a marker for a complex mixture.

3. Were potentially confounding exposures measured or estimated?

In the original teamster study, next of kin of the cases and controls were interviewed about the subject's smoking, dietary, and asbestos exposures. Work histories included employment in any previous diesel-exposed job. The analysis used information from next of kin to control for smoking and asbestos exposure. Spatial and temporal variations in individual exposures to outdoor nondiesel respirable particles and residential indoor air were not assessed. However, these exposures would be of concern only if they related to both diesel exposure and lung cancer.

4. Were magnitude, duration, and variability of exposure determined?

Several aspects of exposure estimation could have considerable impact on the exposure-response analysis. First, in the teamster case-control study (Steenland et al. 1990), exposure was determined by assignment to one of five job (exposure) categories. Each worker was assigned to the category in which he was employed the longest. This method of assigning exposure necessarily restricts a subject to one job, and does not allow for the use of the complete work history or the potentially wide variability of exposure among workers within a job category over time and in different locations. Thus, information on the magnitude, duration, and frequency of exposure to diesel exhaust by the workers was not directly collected or assessed.

Second, recent in-use measurements suggest that newer engines on the road have higher emissions than the engine measurements used by Steenland and colleagues (1998). Extrapolations from recently reported measurements of particulate emissions from in-use heavy-duty vehicle diesel engines suggest that emissions were about 5 grams per mile through 1980 and then began to fall as new technology was introduced, with the fleet average falling to about 2 grams per mile in 1990 (Graboski et al. 1998). This differs from Figure 3 in Steenland and colleagues (1998), which shows lower emission estimates for each of three different scenarios of changing emissions over time.

Third, dieselization was assumed to begin in 1949. However, the proportion of the fleet that was diesel-powered increased gradually until the 1970s, by which time most heavy-duty trucks sold were diesel-powered. Exposures to diesel engine emissions in the early years would not have been as great as later in the study period.

Fourth, the emissions data for heavy-duty trucks were linked to the industrial hygiene data for the various job categories, and this exposure was scaled to heavy-duty truck VMT. These assumptions need to be explored further. Linking emissions from heavy-duty trucks to off-road job categories, such as dock workers and mechanics, is probably not the most appropriate method to estimate those workers' exposures. Working environments on loading docks and in repair shops, particularly ventilation and temperature, can affect exposure estimates and are not accounted for in this approach to estimating exposure. Also, increasing VMT does not necessarily mean increasing exposures for these workers; more likely it means hiring more workers handle the additional work. How the heavy-duty truck emissions and VMT assumptions interact and affect exposure estimates applied to other job categories requires further investigation.

Fifth, the estimation of relatively high roadside and background exposures may overestimate ambient exposures.

In summary, the estimated historical exposures to diesel emissions are associated with several major uncertainties (Steenland et al. 1998), t e effects of which are difficult to estimate. The impact of varying the uncertainties associated with the assumptions needs to be addressed.

5. Were industrial hygiene data and historical data on use and repair of machinery and equipment obtained?

Historical exposures (Steenland et al. 1998) were estimated by combining an estimate of reduction in emissions from improved technology and fuels with the increase in emissions from the increased use of diesel engines and fuel. The reduction in emissions was taken from estimates made by Sawyer and Johnson (1995) of new engine particulate emissions for three broad time periods, the 1970s, 1980s, and 1990s. These data were incorrectly applied to the diesel truck fleet; because vehicle turnover time is long and particulate emissions increase with vehicle age, the fleet average emissions (which determine exposure) are always greater than the new engine technology. In-use truck emissions data are now available that could provide a better estimate of truck emissions (Graboski et al. 1998). Included are emission measurements from trucks that predate emission controls; these data could possibly be useful in establishing emissions relevant to the 1959–1983 exposures studied by Steenland and colleagues (1990).

6. Were personal exposure measurements obtained, and were they representative of the population studied?

The industrial hygiene study (Zaebst et al. 1991) provided information useful in identifying job categories in which teamsters might be at risk of exposure to diesel exhaust. Researchers developed a specific marker for diesel exhaust, EC_1, and demonstrated that ETS, a major source of respirable particle mass, did not interfere in its measurement.

The specific methods by which they selected breakbulk truck terminals and individual teamsters for air sampling were not described. The investigators appear to have collected a convenience sample rather than a random sample, so any inferences applied from these results to truck terminals and to teamsters across the country are uncertain. A statistically drawn sample from terminals and teamsters nationwide would have been desirable, although perhaps not feasible.

Individuals and sites were not sampled repeatedly, which makes it difficult to assess individual or fixed-site variability in exposure. Long-haul drivers in this study may not be representative of all such drivers, because only "short turn-around" drivers were sampled (drivers who returned to the originating terminal 10 to 12 hours after departing from it). Finally, the cut point of 10°C used in this analysis to represent climate effects on diesel exhaust exposure for teamsters is not well supported, and may introduce considerable uncertainty.

7. Were uncertainties in exposure assessment quantified?

The investigators used three different emissions models to represent changes in exposure over time, and they found that their primary conclusions did not change (Steenland et al. 1998). The major sources of error in estimating exposures to diesel exhaust have not been identified or critically evaluated. There is likely to be considerable uncertainty associated with the exposure categories into which workers were placed, and that uncertainty is likely to affect the findings of the case-control study as well as a QRA. The Panel did not extensively evaluate the assumptions in the report because of time constraints; however, this is an aspect that others can pursue.

OUTCOMES

1. Were outcomes defined in specific and objective terms?

The investigators clearly described the outcome as lung cancer identified on death certificates as an underlying or contributory cause of death.

2. Was the full range of outcomes included in cohort studies?

This is not applicable, because the teamster study was a case-control study of lung cancer.

3. Were participants actively followed to determine outcome status and the date outcome occurred?

This is not a cohort study. However, if personnel records or deaths of teamsters were missing from the Central States Teamsters Union files, results could have been biased. Information on the completeness of these files was not given in the original publication of the case-control study (Steenland et al. 1990).

ANALYSIS

1. Were analytic methods specified a priori?

There is no indication that the results obtained by using various exposure measures were explored before exposure-response analyses were conducted or that observed outcomes influenced the analyses.

2. Was the appropriateness of the statistical approach demonstrated and were potential biases explored?

Steenland and colleagues (1990) adjusted their statistical analyses by introducing categorical variables for age, race, smoking status, diet, and reported asbestos exposure. It appears that possible interactions among these variables were not investigated. All deaths occurred in 1982 and 1983, so there was no need to adjust for calendar year.

3. Were exposure-response relations statistically explored?

In the Steenland and colleagues (1998) analysis of an exposure-response association, average emissions per diesel vehicle were combined with historical information on heavy-duty truck VMT and the 1991 industrial hygiene measurements (Zaebst et al. 1991) to estimate past exposures for each job category. This assumption implies that estimating exposures in this way appropriately reflects exposures in the various job categories. However, the uncertainties of the assumptions involved were not adequately justified. Although the estimated exposures were reasonably proportional to fleet average emissions, it is not clear that they scale well with VMT, especially for off-road occupations. One might expect that the exposures of dock workers and mechanics would be independent of VMT, but related proportionally to the number of trucks coming to the dock and the number needing work by mechanics, if each truck driver is driving the same average distance per day. (The potential problems with the exposure estimation are discussed under Exposure Assessment, Question #4.) How the various assumptions regarding emission levels, timing of dieselization, and use of VMT interact and vary with, relate to, and affect the exposure-response analysis was not explored. It is possible that once the assumptions used to estimate exposure are reviewed and evaluated in the exposure-response analysis, the net impact of over- and underestimations will in fact be small; however, this issue needs to be explored. Figure 9 depicts the increasing use of diesel fuel as a fraction of all fuels used by vehicles since 1949.

To account for fleet turnover, the investigators conducted separate analyses with both zero- and five-year lags, and found similar results (Steenland et al. 1998). Actual fleet turnover time is likely to be much greater than five years, however; therefore, longer lag periods need to be explored. Steenland included a large number of covariates and reported goodness of fit of the final model, but effect modification was not explored. There is only limited discussion of how using other exposure-response functions might affect risk assessment, although the shape of the exposure-response function was evaluated in detail.

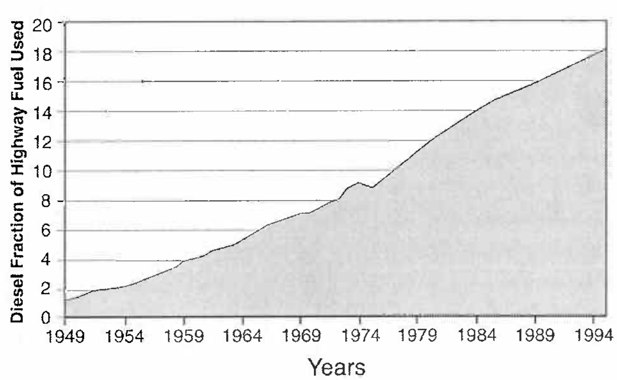

Figure 9. The increasing use of diesel fuel as a percentage of all fuels used by highway vehicles since 1949 in the U.S. (Adapted from Davis 1998.)

4. **Were uncertainties in risk estimates quantified, especially those resulting from exposure measurement error?**

The investigators discussed various sources of uncertainty, but did not evaluate them quantitatively, nor did they develop an overall quantitative estimate of uncertainty from all sources. How uncertainties in the emissions and exposure measurements propagate through the exposure model is complex, but methods exist to assess such uncertainty.

To a limited extent, the dependence of the estimated exposure-response relation on assumptions about the exposure model was explored by conducting analyses with increased exposures for long-haul drivers, and by using three assumptions about the decrease in emissions since 1970. The investigators' publication does not include analyses that fully reflect most potential biases and uncertainties in exposure estimates; however, it concludes with appropriate statements about the uncertainties in exposure estimates.

DISCUSSION OF USING TEAMSTER DATA FOR QUANTITATIVE RISK ASSESSMENT

The Panel concludes that a strength of the exposure-response analyses of the teamster data is in the apparent relevance of the diesel exhaust exposure levels to those of the general population (Zaebst et al. 1991), indicating that truck drivers are exposed annually to about 4 µg/m^3, roadside exposures are about 2.5 µg/m^3, and residential exposures are about 1 µg/m^3. The estimated annual exposure of long-haul truck drivers is not far above that of the general population. Heavy-duty trucks are one of the major sources of the general population's exposure to diesel emissions, so the assessment of risk for truck drivers is relevant to assessment of risk for the general population. Exposure assessment on the basis of elemental carbon provides a measure that is a reasonable marker for DPM, an improvement over previous assessments utilizing total respirable particulates.

The Panel believes that the assumptions used in the exposure assessment (Steenland et al. 1998) should be extended and validated, particularly to account for variations in diesel exhaust levels over time and improved estimation methods. The quantitative exposure portion of this study is new to the literature and, unlike the railroad worker studies, it has not undergone the extensive post-publication peer review that is required to develop a fuller understanding of the data. In fact, Steenland and colleagues (1998) concluded their findings by stating: "Our results should be regarded with appropriate caution because our exposure estimates are based on broad assumptions rather than actual measurements."

The Panel has some specific concerns regarding the exposure-response analysis assumptions and how the associated uncertainties in each assumption affect estimates of exposure. First, estimating exposure using previous 1990 emissions data may underestimate exposures given recent data from in-use vehicles that indicate emission levels of new diesel engines may in fact be higher than previous measurements made from an engine dynamometer, which were used in the study by Steenland and colleagues. Second, determining the onset of dieselization needs to be reconsidered because fewer diesel vehicles on the road in the early years would mean proportionally less diesel exhaust exposure during that time.

Third, the degree to which VMT accurately reflects the proportion of exposure for the various job categories needs more detailed exploration. More VMT by heavy-duty vehicles does not necessarily mean that exposures for dock workers and mechanics working on those trucks increase proportionately with the extra miles traveled. Instead, the VMT increase is likely to mean more dock workers and mechanics, rather than higher exposures per person.

Fourth, the analytic models did not explore the use of longer lag periods to account for the slow turnover of vehicles in use. A five-year lag is unlikely to be sufficient to account for fleet turnover, which may take closer to 20 years. Fifth, nondiesel sources of elemental carbon were not considered in the exposure assessment. Although elemental carbon from stationary sources may be decreasing in the air over time, recent findings indicate a substantial elemental carbon contribution from gasoline engines that should not be ignored (NFRAQS 1998). Finally, a background level of exposure was fairly similar to levels of exposure for the drivers, and sorting out the differences could be difficult.

The Panel speculated that controls selected for use in the case-control study of teamsters might have been biased in ways that could affect the findings. Exploring the distribution of causes of death among controls by smoking and exposure status could help clarify the possibility of selection bias and confounding in the data. Although no direct evidence of such bias is apparent, the Panel offers hypothetical examples showing the effect of potential bias in case-control studies with deaths from "other causes" (depicted as CVD because most of the "other causes" were probably CVD deaths) under different scenarios in Appendix D. Even though these examples suggest that case-control studies that use "other" causes of death could produce misleading results, it is important to note that they are only hypothetical examples. Whether or not such bias is present will require further examination.

The postpublication peer review of a potentially important study can be a long, laborious, and uncertain process. It took several years of work by both the original investigators and independent analysts to learn much of importance about the railroad worker study. This process can and should be accelerated for the teamster study, particularly given the apparent relevance of the data to ambient exposures. When reviewed by the original investigators and other analysts, these data may reveal new issues and raise new points for discussion in the scientific and risk assessment communities.

Findings and Recommendations for Future Research

The Diesel Epidemiology Expert Panel was charged to (1) review the epidemiologic data that form the basis of current QRAs for diesel exhaust, (2) identify data gaps and sources of uncertainty, (3) make recommendations about the usefulness of extending or conducting further analyses of existing data sets, and (4) make recommendations for the design of new studies that would provide a stronger basis for risk assessment. The Panel was not charged to evaluate the broad epidemiologic literature concerning exposure to diesel exhaust and lung cancer for hazard identification purposes. The Panel's review of the epidemiology focused on the railroad worker (Garshick et al. 1987, 1988) and teamster (Steenland et al. 1990, 1992) studies because these studies have been used or considered for use in QRA, and other epidemiologic studies did not have associated quantitative exposure data. The Panel also reviewed published exposure-response analyses of the railroad worker data (Crump et al. 1991; OEHHA 1994, 1998; Crump 1999) and teamster data (Steenland et al. 1998), along with published industrial hygiene studies (Hammond et al. 1988; Woskie et al. 1988a,b; Zaebst et al. 1991). The Panel's findings are based on examination of these studies only, and not on the entire epidemiologic literature in this area.

The Panel recognized that no epidemiologic study can be perfect. Therefore, the Panel viewed its task as addressing the question: To what extent can limitations in the design and performance of a particular study affect its contribution to the body of epidemiologic knowledge under examination for QRA? The Panel also recognized that frequently it is very difficult to obtain retrospective data for estimating job-related work exposures, and that this process may require assumptions that cannot be validated. In the studies considered here, which form the core of the Panel's review, investigators made reasonable attempts to reconstruct past exposures to diesel engine emissions, using approaches that were feasible when the studies were conducted. These data have subsequently been used, in some cases, for purposes that were not envisioned by the original investigators.

Evaluation, reanalysis, and scrutiny of research reports bring new understanding. This report, including the evaluation, findings, and recommendations, is not meant to be the "last word" in this matter. Instead, it is meant to inform HEI and others about data needs and future research directions, including where improvements can be made on the basis of what has been learned from the limitations of currently available studies.

Important work is currently under way to study the effects of exposure to diesel exhaust among nonmetal miners in Germany (Säverin et al. 1998) and in the United States (NCI-NIOSH 1997). These studies were not reviewed because they are still in progress. However, the Panel heard presentations from these investigators at the HEI Diesel Workshop: Building a Research Strategy to Improve Risk Assessment (HEI 1999) at Stone Mountain, GA, March 7–9, 1999. In particular, the NCI-NIOSH study is large and appears to be well designed and comprehensive. It includes a cohort and nested case-control component, as well as extensive measurements of current exposure to diesel exhaust, detailed reconstruction of historical exposure, and biomarker development. When completed, these studies are likely to inform hazard identification, exposure estimation, and exposure-response analyses, all components of risk assessments.

The Panel recognizes that regulatory decisions need to be made in spite of the limitations and uncertainties of the few studies with quantitative data currently available. The findings described here and the systematic evaluation of these studies are designed to provide a means to weigh a study's strengths and limitations and to inform the QRA process.

FINDINGS

GENERAL

Enhanced exposure and epidemiologic data and analyses are needed for the purposes of QRA; these might come from further exploration of existing studies or from new studies.

RAILROAD WORKER STUDIES

At present, the railroad worker cohort study (Garshick et al. 1988), though part of a larger body of *hazard identification studies, has very limited utility for QRA of lifetime lung cancer risk from exposure to ambient levels of diesel exhaust for the following reasons.*

- The various exposure-response analyses are limited by the scope and quality of currently available exposure data. Quantitative exposure data were not obtained during the cohort study period. Also, there is a paucity of qualitative data on individual exposures before 1959, and on the variation in exposure by railroad site, by season, and over time. The potential impact of concurrent exposures (for example, to grease, dust, other fumes, asbestos, and active and passive cigarette smoke) was not examined in depth. The diesel exhaust exposure data are suitable for a crude categorical measure of exposure by job category; but other measures, including duration of employment in a job category exposed to diesel exhaust, intensity of exposure concentration ($\mu g/m^3$), and lifetime exposure ([$\mu g/m^3$]-years), are not adequate to support quantitative exposure-response analyses.
- The Panel's analysis of the exposure-response association in the railroad worker data showed that the evidence for a positive association of lung cancer with cumulative exposure to diesel exhaust depends entirely on differences in risks among job categories. Train workers (with higher exposures) have higher risks compared with clerks (with low or no exposure). However, within all job categories, the relation of lung cancer risk to duration of employment is negative.
- Factors that might explain a negative association between duration of employment and lung cancer in these data include bias introduced by systematic differences in exposure misclassification among and within job categories; differentially incomplete ascertainment of lung cancer deaths by job category; lack of information on other occupational exposures and air pollutants; the presence of a healthy worker survivor effect; confounding by cigarette smoking; and analysis of relative risks rather than absolute risks. Also, in a case-control study, if causes of death among controls were associated with exposure to diesel exhaust, smoking, or both, the results could be biased.

TEAMSTER STUDIES

The investigators' analysis of the teamster data reported an exposure-response relation (Steenland et al. 1998) that may be useful for QRA; this relation will be better understood with further exploration of uncertainties and assumptions, particularly those relating to the reconstruction of past exposures and the selection of controls. Exposures of teamsters are more similar to ambient exposures of the public than are exposures of railroad workers, and the diesel exhaust to which teamsters are exposed comes from a source that is likely to be relevant to regulatory issues.

The Panel reviewed the teamster study without the benefit of additional analyses and interpretations, and its comments are not as detailed as those about the railroad worker studies. Understanding the teamster study will evolve with time; however, some conclusions can be drawn now.

- The set of teamster studies may provide reasonable estimates of worker exposure to diesel exhaust, but significant further evaluation and development are needed. The marker for diesel exhaust that was selected for study by Steenland and associates, EC_1, is more sensitive and specific than RSP adjusted for environmental tobacco smoke, but has several limitations (e.g., the contribution of diesel emissions to ambient EC_1 concentrations has not been constant over time). The industrial hygiene study, which was conducted after the period when workers in the case-control study were exposed, identified a range of exposures for various job categories, but did not consider (1) site-to-site variations, (2) seasonal variations, (3) concurrent exposures to other agents, (4) historical ambient particle concentrations, or (5) intra- and interindividual variability. The estimation of historical exposures needs to incorporate recent data on diesel emissions from vehicles in use, reassessment of when dieselization occurred, alternatives to estimating exposure by vehicle miles traveled, and historical regional ambient pollution data.
- The exposure-response relation reported in the teamster study increases in a linear manner. However, more can be learned from other analysts examining these data using different approaches.
- Neither a roster of the study population nor an alternative method of selecting controls to represent it was available to the researchers. It cannot be established with certainty whether the causes of death used for controls adequately represent the joint distribution of exposure to diesel exhaust and smoking in the case-control study. If smoking, or diesel exhaust exposure as determined by job category, or both were associated with causes of death used for controls, results could be biased.

RECOMMENDATIONS

The Panel's recommendations reflect its general understanding, as expressed in its framework for evaluating studies, of what constitute adequate data for QRA. They also reflect the preceding evaluation of the studies of railroad workers and teamsters. The Panel is aware that research currently in progress will respond to some of these research needs; however, results are not yet available, and it is not yet clear whether all of the proposed needs will be met.

COMPLETED STUDIES

1. The Panel recommends against using the current railroad worker data as the basis for QRA in ambient settings.
2. Further scrutiny of the teamster data, including estimation of uncertainty in both the exposure estimates and selection of controls, is recommended in order to improve the use of these data in QRA. Strengths of the teamster study include the relevance of exposure levels to the general population and the use of an exposure marker for diesel engine emissions that was an improvement over RSP. The teamster study exposure-response analysis is relatively new, and its further review and analysis by both the original investigators and others should be accelerated. Alternative retrospective exposure models need to be developed that use the alternative assumptions described above and in more detail in the body of the text.

NEEDS FOR NEW TECHNIQUES AND DATA

3. Better measures of exposure to constituents of diesel emissions, with careful attention to selection of the sample studied, are needed. Of particular importance are the selection and validation of a chemical marker of exposure to the complex mix of diesel exhaust emissions. Exposure models may include data from personal monitors, area monitors placed where diesel exposure is likely to occur, and current and historical data regarding emission sources. In any such modeling effort, the effects of environmental tobacco smoke should be removed as completely as possible.
4. Reliable estimates of past emissions and of factors affecting historical exposures in a range of settings are needed to improve the characterization of uncertainties, both quantitative and qualitative, in historical models of exposures.
5. Although biomarker technology was not available when the studies reviewed were conducted, appropriate, validated, and specific biomarkers of diesel exposures, health outcomes, and susceptibility are needed.

DESIGN NEEDS FOR NEW STUDIES OF EXPOSURE-RESPONSE ANALYSES

6. Exposures should be adequately and accurately characterized with respect to magnitude, frequency, and duration, rather than solely by duration of employment. Errors and uncertainties in exposure measurements should be quantified where possible; these should be fully reported to users, and taken into account in both power calculations and exposure-response analyses.
7. Cigarette smoking is a potent risk factor for lung cancer, and it must be controlled for in any study of risk factors for this disease. Smoking histories obtained for a cohort study subset that uses a case-control or case-cohort design will strengthen the interpretation of results.
8. The exposures considered should be close to levels of regulatory concern, including a range of exposures to provide a base for understanding the relation between exposure and health effects.

NEEDS FOR NEW STUDIES

A prospective epidemiologic study of the development of lung cancer in exposed and unexposed individuals could have many strengths. Information on confounders and exposures could be more complete than for a retrospective study, and many of the biases and uncertainties discussed in this report could be eliminated or reduced. These advantages, however, need to be weighed against the disadvantages, which include high costs and a long period of follow-up. Other study designs that include retrospective components, are possible for a new epidemiologic study of lung cancer, but they are likely to include uncertainties and sources of bias that investigators will need to explore completely and acknowledge in their reporting.

9. The Panel recommends that a new, large, epidemiologic study of diesel exhaust emissions and lung cancer be considered after (1) currently ongoing or existing studies, including HEI's feasibility studies (to be completed in the spring of 2000), are evaluated, and (2) attempts to retrofit improved exposure assessments to existing epidemiologic studies are evaluated, including whether they can provide sufficiently accurate, complete, and relevant exposure data to support QRA.
10. Studies of lung cancer risk in general populations exposed to ambient diesel exhaust particulate matter will be difficult to conduct; however, such studies could usefully investigate other, noncancer health effects that occur in a shorter time after exposure.

Appendices

Appendix A. Diesel Epidemiology Expert Panel Workshop

WORKSHOP AGENDA FOR APRIL 20, 1998

Introductory Remarks *John Bailar* and *Kathleen Nauss*

Summary of the Design and Results of the U.S. Railroad Worker Studies and Issues Raised Using These Data for Dose-Response Analysis *Eric Garshick* and *Thomas Smith*

Questions on the Study Design and Results of the Railroad Worker Study

Analyses of Dose-Response Based on the U.S. Railroad Worker Cohort Study

- Discussion of Key Assumptions and Main Findings of Original Analysts *Kenny Crump* and *Stanley Dawson*
- Questions for Drs. Crump and Dawson
- Perspectives of Other Analysts *Duncan Thomas* and *Suresh Moolgavkar*
- New Analyses *Leslie Stayner* and *Dale Hattis*
- Questions for Drs. Stayner and Hattis

General Discussion of Approaches for Developing Dose-Response Estimates for Diesel Exhaust and Lung Cancer Based on the Railroad Worker Studies

Alternatives to the Railroad Worker Studies: U.S. Truck Driver Studies *Kyle Steenland*

- Questions and Discussion of Truck Driver Analysis

General Discussion

WORKSHOP PARTICIPANTS

DIESEL EPIDEMIOLOGY EXPERT PANEL

John C. Bailar, III (Chair)
Department of Health Studies, The University of Chicago, Chicago, IL, and the HEI Health Review Committee

Ethel Gilbert
Radiation Epidemiology Branch, National Cancer Institute, Rockville, MD

David Hoel
Department of Biometry and Epidemiology, Medical University of South Carolina, Charleston, SC

Brian Leaderer
Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT

Charles Poole

Appendix B. Framework for Systematically Evaluating Epidemiologic Studies for Quantitative Risk Assessment

The Panel developed a framework of epidemiologic principles, with a focus on exposure assessment, for the systematic evaluation of the strengths and limitations of the railroad worker and teamster epidemiologic studies. It designed a set of questions representing an ideal research strategy, and emphasized that a "perfect score" was not the objective. The Panel did not assign overall priorities to these principles, because insisting that any one be given absolute priority over another may interfere with efforts to manage or address other principles in a more balanced fashion.

The Panel recognized that others have written on the use and limitations of epidemiologic studies for QRA (Gordis 1988; Hertz-Picciotto 1995; Samet et al. 1998). However, it chose to develop this series of questions in order to address specifically the issues it believed would be most relevant to systematic assessment of gaps in current knowledge that might be filled by future research efforts. The Panel also recognized that few, if any, epidemiologic studies are designed specifically for QRA, and the framework allows potential users of available studies a somewhat parallel approach to evaluating the strengths and limitations of each. This Appendix offers details and some rationale for including each of the items within the framework.

This framework also provides some basic concepts of epidemiology for readers unfamiliar with such material. For a more complete understanding of epidemiologic study designs and methods, several general texts in epidemiology are available (Monson 1980; Schlesselman 1982; Checkoway et al. 1989; Hulka et al. 1990; Selvin 1991; Gordis 1996; Kelsey 1996; Rothman and Greenland 1998). The Panel assumed that any epidemiologic study would follow standard epidemiologic practices as discussed in these texts.

DESIGN

1. **Was the study design efficient, and did it specifically consider power, potential types of bias, and latency?**

Epidemiologic studies need time to recruit subjects, an adequate latent period for the health outcome of interest to develop, and sufficient time for the accrual of substantial follow-up during any period of elevated risk. Study design considerations include cohort and case-control designs, the choice of study population, and the selection of controls. An efficient study design that allows more detailed characterization of exposure in all or a subgroup of the cohort, as well as collection of personal data such as smoking history, generally may be useful for a QRA. A simple design is the nested case-control study, but more complex designs also merit consideration. Although these efficient designs allow collection of details that might be otherwise unattainable, epidemiologic studies without them can still be useful in QRA.

Determination of the statistical power needed to address questions of interest is an important aspect of study design; adequate power for analyses of subgroups within the population also needs consideration. The design, including sample size, must make adequate allowance for factors that reduce power (such as losses to follow-up and uncertainties in exposure measurements) and at the same time minimize potential biases. If the sample size is insufficient, statistical power is low and the association under investigation is unlikely to be detected. It is useful to calculate the statistical power for detecting effects of various magnitudes, and to indicate the precision with which effects can be estimated, including the size of the effect that might be excluded (upper confidence limit). Exposure measurement errors, which can reduce both power and estimates of precision, need to be taken into account. Reasonable assumptions about latency are a part of most power calculations. For cohort studies, it is desirable to present power as a function of the duration of follow-up. Cohort studies that continue follow-up as long as subjects provide usable new information can be particularly beneficial to QRA.

The study design should reduce or control for several important biases including confounding, information bias, and selection biases. The contribution of an individual epidemiologic study to the body of literature for hazard identification depends on whether the statistical power of the study is sufficiently large to detect an effect and provides a degree of precision to that estimate as indicated by the width of the confidence interval. It also depends on whether the study design, data collection, and statistical analyses have reduced the potential sources of bias.

Confounding is a form of bias that occurs when a factor is associated with both the exposure and the outcome of interest. This factor is referred to as a confounding variable or confounder. In studies of lung cancer associated with exposure to diesel exhaust, the potential confounders of importance include age, cigarette smoking, ETS, asbestos exposure, other occupational exposures, and possibly nondiesel outdoor air pollution, but only if the factor is related to both diesel exposure and lung cancer risk. The effects of demographic variables such as age can generally be removed during the analysis, but adjustments for variables such as smoking and exposure to asbestos are not possible in the absence of adequate data on these factors. Information on the degree of possible confounding sometimes can be gleaned from considering causes of death other than the one of primary interest.

The direction of the effect of confounding depends on the directions of the associations between the confounder and the exposure, and between the confounder and the disease. Cigarette smoking, for instance, is widely acknowledged to be positively associated with lung cancer. Thus, if smoking is more common among persons exposed to diesel exhaust than among unexposed persons, the confounding would lead to overestimation of the risk of cancer associated with diesel exhaust. Conversely, if the group exposed to diesel exhaust smokes less than those unexposed, the confounding would lead to underestimation of risk.

Information bias refers to differential errors in measurement of exposure, outcome, or confounder information between groups being compared. For example, if the extent of information available or obtained for exposed persons differs from that for unexposed persons, an information bias would occur.

Misclassification is another form of potential bias in epidemiology that occurs, for example, when a control subject in fact has the outcome of interest. Misclassification can be either differential or nondifferential. In differential misclassification, the rate of misclassification differs by study group; for example, the fact of exposure may be wrong more often for cases than for controls. Nondifferential misclassification is the inaccurate classification of exposure or disease that is not dependent on any factor, such as case or control status. Differential misclassification can bias the estimate of risk in any direction, but nondifferential misclassification most often leads to an overall underestimation of effect. Some forms of misclassification can distort the shape of the exposure-response curve.

Selection bias results from a systematic difference in characteristics of subjects included in a study and is most likely to occur when choosing controls for case-control studies. Selection bias also is possible in cohort studies if, for instance, a cohort is assembled in such a way that completeness of follow-up for lung cancer differs by exposure. (Refer to Appendix D for further discussion of this matter.)

Submittal and selection of a study for publication in a journal, as well as the failure of a study to be published, can result in a form of selection bias. Editors as well as investigators often are reluctant to publish results that do not appear to show an effect, and they are extremely reluctant to publish results that appear to show implausible associations (such as inverse associations between exposure and health outcome). In a research field consisting of dozens of studies, however, a few such results are inevitable.

It is well established that persons in the work force tend to be "healthier" than persons not employed, and therefore healthier than the general population. Worker mortality tends to be below average for all major causes of death. Mortality in the general population thus is generally not a suitable standard for comparison in occupational studies, and can lead to biased findings. Because of this "healthy worker effect," investigators often compare morbidity or mortality of heavily exposed workers with workers in the same industry who have little or no exposure.

Some investigators also have reported a "healthy worker survivor effect" (Arrighi and Hertz-Picciotto 1994), in which mortality of long-term employees in some occupations is less than in those with shorter employment duration. This may seem counterintuitive because, if an association exists, one would expect mortality to increase with longer employment, which then becomes a surrogate for both age and accumulated exposure. Reasons for this survivor effect are not clear, but may include early demise or departure from the work force of some susceptible individuals.

The study design chosen needs to allow for an adequate latent period for developing the health outcome of interest after exposure to the risk factors studied. For some cancers, the latent period may be 20 to 40 years (Cold Spring Harbor Laboratory 1981). Latency period, timing of exposures, duration of exposures, and exposure-response measures are all interlinked, and all are essential to a complete assessment of risk. Exposure duration might provide a reasonable surrogate for exposure, although the investigator might not have data to convert duration into units of exposure. An additional limitation of this approach is that exposure duration does not reflect any variation of the intensity of exposure with time or among subjects.

Addressing the biases above strengthens a study's possible contribution to both hazard identification and QRA.

2. Were adequate quantitative exposure and covariate data planned and collected?

The Exposure Assessment section below has more details on exposure assessment and data collection. Exposure data generally are collected as part of epidemiologic studies, but the degree of quantification of exposure varies. Crude exposure distinctions can be adequate for some purposes, such as hazard identification, but detailed planning for collection of quantitative exposure data is particularly important if a study is to be used for QRA. The exposure assessment plan also informs the analytic plan.

Planning to include data for each study subject with accurate information about the primary exposure of interest, as well as exposure to other known and suspected risk factors, is optimal. In occupational studies without individual monitoring, surrogate measures or markers to estimate exposure can provide useful information. A range of exposures is needed if effects of different magnitude, duration, or frequency are to be compared.

It is important that the study design consider incorporating the variability of personal exposure over time, including multiple samples for the same individual. To the extent that the study design limits exposure measurement for a subsample of the population, it is important to demonstrate that the individuals selected for monitoring reasonably represent the range of activities, behaviors, and exposures of the study population for which the exposure is assessed retrospectively. Exposure data that include the range relevant to regulatory decision-making would be particularly useful for QRA.

3. Was the literature reviewed for relevant study methods and previous research findings?

The literature review can serve to refine and focus a study's hypotheses, support study design decisions, explain analytic approaches, evaluate exposure measures, define the outcome of interest, and identify questions that remain to be answered. A QRA will raise specific issues about exposure measurement, analytic techniques, and outcome measurements that go beyond what is included in the reports from most epidemiologic studies. The literature review needs to specifically address these QRA issues. A thorough review of the literature regarding a possible hazard includes a critical analysis of all epidemiologic studies concerned with the suspected hazard, and a summary of relevant animal studies, exposure studies, and case studies. Information on possible biologic mechanisms of action or variations in individual susceptibility is also important. A summary of the literature surrounding other known and suspected risk factors for the outcome of interest, as well as a summary of current issues within the research topic, can be useful. If unusual, recent, or critical methodological issues are of importance to the area of research, a summary of the pertinent literature also can be useful.

4. Were plans made for postpublication data scrutiny?

While a study is under way, interim reports, scientific critiques midway through the study, and periodic external independent reviews can provide the investigator with useful feedback. After publication, although not an epidemiologic principle, sharing copies of the data and related documentation with colleagues can assist the scientific community and regulatory agencies in understanding the details of a particular study, and can provide a scientific "second opinion" that further evaluates the pertinent issues in an objective manner. Sharing data with other investigators for reanalysis can allow other analytic approaches to be developed, which can be particularly important when published studies do not produce a clear consensus about the magnitude, or sometimes even the direction, of an effect. Such postpublication analyses are most effective when both the original investigator and the recipient of this information hold to the highest standards of collegiality, ensure the integrity of any promise of confidentiality of study subjects, and respect each other's intellectual property rights. The original investigators should have some rights in these circumstances to see any results of further analyses before they are made public.

EXPOSURE ASSESSMENT

1. Were detailed lifetime histories of occupational exposures collected?

Quantitative measures of exposures are important in any epidemiologic study used for QRA. The greater the detail regarding specific exposure, including how much, for how long, and at what concentration, the more useful the study is for this purpose. Frequently, however, individual measures of exposure are not available, and surrogate measures or markers of exposure are used. For example, the most general surrogate measures of exposure in occupational epidemiologic studies are job classification and work location. Starting with a standard classification scheme for job and work location generally is preferred, unless there are specific reasons to replace or supplement the standard with an ad hoc classification. Standard schemes include the U.S. Census Bureau Classified Index of Industries and Occupations, the U.S. Labor Department Dictionary of Occupational Titles and Definitions, and the U.S. Office of Management and Budget Standard Industrial Classification and Standard Occupational Classification. These standard codes can be grouped according to possible exposures. The advantage of beginning with the standard classification systems when quantitative exposure data are not available is that many published mortality studies use such systems, and can provide a basis for comparison. A description of job duties frequently can refine industry and job titles.

Information on the magnitude, frequency, and duration of exposures within each job is desirable and preferable to duration only, but is often unavailable. In many occupational studies, the only exposure information available is duration of employment in specific jobs, which provides a poor estimate of exposure. Thus, the exposure scale in exposure-response analyses of such studies is essentially a detailed analysis of duration of employment. In addition, risk can be related to duration of employment for reasons other than the exposure of interest, thus biasing the exposure-response relation; an example is concurrent exposure to other possibly toxic agents.

The goal of a QRA for regulatory purposes is to estimate an effect of lifetime exposure to the agent of interest. Uncertainties are introduced when exposure magnitude, frequency, and duration are not quantified among job categories; when individual exposure varies primarily because of differences in exposure duration within job category; or when exposures in all of the job categories examined are similar. Although measures of cumulative exposure, which depend on exposure duration, are important for QRA, a study is more informative if available exposure data also allow the effects of exposure intensity and duration to be evaluated separately.

2. Were known chemical and physical characteristics of the main exposure specified?

A detailed characterization of the sources of an agent, valuable to understanding the main exposure of interest, would include specific information (chemical and physical characterization) on the nature and source of the exposure, historical trends, aspects of source use that affect the exposure, and the factors that control transport and transformation of the emitted contaminants indoors and outside. Mixtures of substances are particularly difficult to characterize because they may vary from time to time and place to place in ways that may be difficult to document.

3. Were potentially confounding exposures measured or estimated?

The main exposure of interest often is not isolated in the environment where subjects are exposed. That is, subjects are likely to be exposed to additional agents that may confound or modify the association under investigation; for example, smoking or exposure to ETS would be such factors in many studies.

Some studies of occupational exposures have investigated confounding by smoking. Results have been mixed—some produce evidence of confounding and some do not. A nonsignificant *p* value does not demonstrate that no confounding occurred, though confidence limits on a confounder effect might provide useful information about the greatest degree of confounding that would be generally consistent with the data. For example, smoking might not appear to be a confounder for a particular occupational exposure, but a study is open to criticism if no smoking data are collected and the association between exposure and outcome is weak. In addition to being a confounder, smoking may be an effect modifier, in that the estimated increase in risk of lung cancer from diesel exhaust may differ between smokers and nonsmokers. Smoking data are necessary to allow effect modification to be investigated.

Measurements of confounders are needed to understand their potential effects on the analysis of the exposure of interest. Failure to account for possible confounding or effect modification by other exposures might mask a real (positive or negative) association. When the magnitude of the association of interest is weak, uncontrolled confounding, particularly from a strong confounder such as cigarette smoking, can have a major impact on the study's results and on the credibility of their use.

4. Were magnitude, duration, and variability of exposure determined?

Studies with quantified individual exposure data contribute more to a QRA than studies without such data. Because personal exposure varies over time, sampling the same individual multiple times to capture various seasons, activities, and work place settings is preferable to obtaining a single sample. Multiple measurements during episodes of peak exposure, as well as collecting data for subgroups of interest, are often important.

Historical or current source emission data, when combined with factors that govern the dispersal and removal of contaminants in the environment (meteorological variables, ventilation, dry or wet deposition, chemical transformations, etc.), can be modeled to assess air contaminant concentrations in particular air environments, which in turn can be used to assess individual or group exposures over time. Air contaminant measurements that have been made in several different environments can be used to assess such exposures directly. If an historical record of environmental measurements exists, past exposures associated with a particular environment can be assessed. Estimates of total exposure can be based on either measured or estimated concentrations within each outdoor or indoor environment, combined with time-activity observations or questionnaire data. Uncertainty is associated with using environmental measurements to assess exposure, however, and the source and magnitude of that uncertainty needs to be specified.

5. Were industrial hygiene data and historical data on use and repair of machinery and equipment obtained?

A critical review of the historical records on the nature and chemical characterization of exposure and environmental monitoring data can add to the exposure assessment and improve historical reconstruction estimates. In addition to historical records of measured exposures (specific to an employer), records on the purchase and maintenance of equipment, the industrial processes resulting in exposure, and repair shop operations can provide information to help define historical exposure levels and trends by industry.

6. Were personal exposure measurements obtained, and were they representative of the population studied?

Personal monitoring for inhaled exposures is conducted using either passive (diffusion) or active (pump) samplers worn in the breathing zone to measure exposure to contaminants of interest as people go about their daily activities. Subjects typically wear the monitors for periods of a few hours to several days to provide an integrated measure of exposure over space and time. Personal monitoring can reduce some of the uncertainty in exposure assessment; however, continuous monitoring cannot distinguish among exposures that occur in different indoor and outdoor environments or among different activities in which the subjects are involved.

It usually is not practical or cost-effective to conduct personal monitoring on all subjects. Supplementary questionnaire-derived information, environmental models, and daily activity diaries usually are needed to estimate the contribution of specific environments, activities, or sources to the total exposure.

Special care must be taken in selecting a sample of subjects for personal monitoring because exposures may vary widely within job categories and for an individual over time. A random sample of subjects can be selected in various ways to ensure that it is representative of the entire population under study (e.g., a simple random sample of individuals, stratified sampling based on job environments or job categories, random cluster sampling). Nonrandom samples, especially convenience or quota samples drawn to address specific questions, are sometimes useful but always difficult to interpret, and they produce results of greater uncertainty than properly designed random samples. The process used to select the sample and to document that it is representative of the study population need to be stated clearly and in some detail, especially for nonrandom samples.

7. Were uncertainties in exposure assessment quantified?

Exposure assessment should include quantification of the uncertainty in each aspect of the assessment, as well as the overall uncertainty in estimates of exposure. These uncertainties are likely to vary among subjects (or categories of subjects). Sources of uncertainty that are the same (or strongly correlated) for subjects within a category should be separated from sources that are independent. For many components of the exposure assessment, quantitative estimates of uncertainty are necessarily based on subjective judgments. To ensure that the resulting evaluation of uncertainty is useful for interpreting the exposure-response analyses, it is suggested that exposure assessors work closely with the epidemiologists and statisticians analyzing the epidemiologic data. (Refer to Analysis Question 3 below.)

OUTCOMES

1. Were outcomes defined in specific and objective terms?

Criteria for health outcomes in a study are less subject to bias if the definitions are accurate, specific, attainable, and as objective as possible. A study is less likely to be biased if the outcome is not subject to possible misclassification. For example, the operational definition for cancer can be a tissue specimen or pathologic diagnosis (most accurate), a clinical diagnosis (less accurate), or a death certificate (least accurate).

2. Was the full range of outcomes included in cohort studies?

Cohort studies rely on various sources of information and record-keeping systems to define and identify subjects having the outcome of interest. A by-product of this is obtaining information about a range of other health conditions. For example, if death certificates are examined for a possible relation between some exposure and death from a particular cancer, the certificates of all deceased subjects must be searched to find those that report the cancer. With little additional effort, the full range of causes of death can be examined. Relevant information on death certificates may include any underlying causes of death, as well as the primary cause of death.

3. Were participants actively followed to determine outcome status and the date outcome occurred?

A clear statement of the cohort follow-up methods is needed. Active follow-up of study participants to determine their health outcome and its date, as well as the determination of a subject as "outcome free," or the date a participant was last known to be "outcome free," can be important for reducing bias. Active follow-up strengthens a study's findings because confirmation of the outcome is sought, and the information acquired is more complete and generally less biased than with passive follow-up. Subjects determined to be "lost to follow-up" are usually assigned a date corresponding to the last date they were confirmed to be "outcome free." If the follow-up is passive, subjects not identified as having the outcome are generally assumed to remain "outcome free." For example, absence of a claim for death benefits may not be adequate evidence that the study subject is still alive. In this situation, a special small study might be undertaken to estimate the number of outcomes that were missed by passive follow-up.

If the percentage of follow-up completed is high, bias tends to be reduced. If a significant number of participants are nonrespondents or lost to follow-up, results can be questionable because of possible misclassification biases, and the number of subjects with unknown outcome may be sufficiently great that the validity of the study findings is questioned.

ANALYSIS

1. Were analytic methods specified a priori?

A study protocol commonly specifies the fundamental hypotheses, but it is equally important to specify the primary methods of analysis the investigators plan to use. Additional analytic techniques, especially those suggested by the data, can supplement the primary methods of analysis, but they lack full statistical justification. A general concern is that analytic methods not specified a priori may be chosen to emphasize some aspect of the findings and, therefore, bias the results. An example would be performing multiple statistical tests of variations and reporting only the most extreme *p* values.

The statement of primary analytic methods specifies the general analytic approaches, software packages to be used, cut off points for continuous variables, exposure metrics, methods of adjustment for age and other confounders, subsets of the data to be analyzed, and exposure-response models.

Exposure data may include several types of measurements, and several possible approaches are likely for assigning exposure estimates to individual subjects. Although analyses based on more than one approach can be informative, it is important to specify the primary exposure metrics before the exposure-response relation is examined.

Defining group categories from continuous data is also important, and these categories should be specified in the protocol rather than determined on the basis of statistical significance levels after the data have been obtained.

2. Was the appropriateness of the statistical approach demonstrated, and were potential biases explored?

An early step in the analysis is to evaluate the appropriateness of the statistical methods specified in the protocol for the primary analyses. This usually involves comparing the fits of various models to establish that analyses based on the model selected do not seriously distort results. The specifics of this evaluation vary from study to study; discussion of a few common types of assumptions follows.

Because lung cancer risk depends on gender, age, calendar year period, and smoking habits, and because estimates of exposure might also vary by these factors, it is important to provide adequate control for these factors in developing quantitative risk estimates. Age and calendar year period can be related strongly to cancer risks as well as to many other health endpoints. In studies (such as occupational studies) in which exposures accumulate over time, exposure also is likely to be related to age and calendar year period. For this reason, analyses need to provide tight control for these variables, and use minimal assumptions regarding the form of their relation to risk of disease. Less flexible models (for example, those that treat age or calendar year as continuous, linear, or exponential variables, or do not include interaction terms) can be considered, but only if it has been demonstrated that they provide an adequate fit to the data.

Analyses are often based on the assumption that the relative risk is constant across strata. This assumption can be evaluated by fitting models that allow relative risks to vary by factors such as age, calendar year period, gender, and time since initial employment. Differences in relative risks might simply reflect differences in the magnitude of exposure; alternatively, other factors may modify sensitivity to a specific exposure. This modification of risk can be important in analyses that quantify the relation between exposure and risk (for example, by estimating the risk per unit of exposure). Risks can be compared among subgroups defined by these variables to investigate these dependencies, or parameters can be introduced to estimate and test the dependencies, or both. However, statistical power and precision for adequately evaluating modifying factors are often limited. Also, whether a factor is considered to modify the risk depends on the metric of risk. For example, if relative risks for lung cancer are similar for smokers and nonsmokers, absolute risks for the two groups can differ substantially.

Absolute risk models often are more difficult to fit; however, they give a direct measure of impact and, therefore, their wider use is suggested. Neither a relative risk model (and its surrogate, the odds ratio) nor an absolute risk model might mirror the biological situation; there is little reason to expect nature to follow any predetermined mathematical structure. Many statistical modeling approaches are available, and the discussion here is not meant to be inclusive. Other types of models, such as nonparametric models (including Kaplan-Meier plots), multistage models of carcinogenesis, or other biologically based models might also be appropriate to consider. However, in the absence of an understanding of the mechanisms for exposure-related carcinogenic risk, it may be difficult to interpret the results of multistage models or other biologically based models. Even when the fit is good, such models generally should be reported as approximations. If evidence of substantial variation is found, it is especially important to fit models that allow for this variation and to present separate results for various subgroups of data.

3. Were exposure-response relations statistically explored?

The exposure-response relation is important to the development of a QRA. In the analysis, the investigators may explore the shape of the relation (e.g., linear), possible modifying factors, and alternative measures of exposure.

Flexible models permit a better understanding of the possible relation between exposure and health outcome. This understanding is valuable for estimating the impact of a particular exposure on a population's health both present and future, as well as for the risk estimation needed to assess and control occupational and environmental hazards.

The effect of a given exposure on risk is likely to depend on the length of time that has passed since the exposure occurred. First, for example, recent exposures are not likely to have affected the risk of diseases with a long latent period (e.g., cancer), so it is often desirable to exclude exposure received during some specified period before the time at risk, known as the lag period. The lag period need not be the same for all endpoints. Even if the protocol has specified lag periods, it is desirable to evaluate their appropriateness by conducting analyses based on alternative lag periods. Second, to evaluate more completely the effect of time since exposure, it might be desirable to include separate variables for the effects in each of several "windows" of exposure (for example, categories of time since exposure such as 5 to 15, 15 to 25, and 25+ years), or to use continuous variables to examine a change in risk with time since exposure. Measures that weight exposures in the various "windows" might also be considered. Third, exposures that vary from time to time, or from one person to another in the same category, may be weighted to reflect actual exposures, but this requires data that are rarely available.

If a specific exposure-response model is proposed (such as a linear model), the assumption of the proposed response form also needs validation. This can be accomplished by comparing the fit with more general parametric models or categorical models. For example, the fit of a linear model can be compared with the fit of a linear-quadratic model or a model in which the risk is related to an estimated power of the exposure.

Often more than one approach is available for defining the exposure metric to be analyzed. Most studies can benefit from collaboration among the data analysts and the persons assessing exposure. Factors to consider include possible bias and uncertainty in the proposed metric and the ability of the metric to discriminate among subjects. The final choice can involve a trade-off of these factors. In an occupational study, for example, duration of employment might be estimated accurately, but exposures among subjects with similar employment duration cannot be differentiated. Measures that use industrial hygiene data to assign quantitative measures to various job categories provide better discrimination among subjects, but are likely to be subject to large uncertainties. Several exposure measures for each subject can be computed and examined for variability and the degree to which they are correlated.

4. Were uncertainties in risk estimates quantified, especially those resulting from exposure measurement error?

Exposure estimates are subject to both systematic bias and random errors. Systematic bias in exposure estimates can affect risk estimates that are expressed per unit of exposure. Random errors in exposure estimates also can result in bias. In general, random errors bias estimated regression coefficients toward the null, although this may not necessarily be true in the special case in which the only error is the substitution of group means for individual measurements (Berkson error). Random errors can also result in both underestimation of uncertainty and distortion of the shape of the exposure-response curve. Statistical analyses can take into account the uncertainties in exposure estimates; however, this is often difficult or impossible in practice, in part because statistical methods for doing so are complex (possibly requiring extensive software development), and in part because it is difficult to quantify potential bias and uncertainty.

Fairly simple procedures sometimes can provide at least some information on the sensitivity of analyses to uncertainties in exposure estimation. One such procedure is to conduct restricted analyses that exclude subjects or job categories thought to have exposure estimates that are especially uncertain or particularly subject to bias. Another is to restrict analyses to workers initially employed after some specified date when exposure assessment is thought to have become more adequate.

Methods for accounting for random errors have been developed, but these procedures are often difficult to apply and can require computer simulations. They also require knowledge of the nature and magnitude of exposure measurement errors, including the extent to which errors are correlated among subjects. Application of such methods might be important even when they are based on overly simple assumptions; sensitivity analyses can then be conducted under several alternative assumptions. Such analyses do not decrease the uncertainty resulting from imperfect dosimetry (only improvements in dosimetry can do that), but they can provide an assessment of the additional uncertainty in the estimated exposure-response relation resulting from this problem.

Sampling error is another source of uncertainty in risk estimates. Confidence intervals and *p* values that describe this uncertainty often are based on the assumption that various statistics follow normal (Gaussian) distributions. Statistical theory provides assurance that this assumption is appropriate provided the sample size is sufficiently large. However, exposure distributions are often highly skewed (nonnormal), and analyses can be affected strongly by a small excess of observations in higher exposure categories. In this situation, the assumption of normality might not be adequate or appropriate. Although they are computationally more cumbersome, *p* values and confidence intervals based on a likelihood ratio statistic often provide better approximations of uncertainty than other approaches (such as the use of the asymptotic standard error). Software that allows reasonably easy implementation of this approach is now available. In some cases, exact methods or computer simulations can be considered.

Appendix C. The Panel's Exploration of Railroad Worker Data

This appendix describes results of the Panel's examination of certain aspects of the original railroad worker data, as presented by Garshick and colleagues (1988). These analyses were undertaken to assist the Panel in evaluating the usefulness of the data for QRA, to help clarify reasons for differences in results obtained by other analysts, and to verify and better understand these other analyses. The Panel's analyses were limited to these objectives, and were not intended to explore or evaluate completely the railroad worker data or to provide a model for QRA. This discussion of results and stated conclusions describes the Panel's findings from its analysis in conjunction with its review of the relevant literature.

DESCRIPTION OF THE DATA

Dr. Eric Garshick provided the basic data in the form of computer records on over 55,000 railroad workers. The Panel used the DATAB module of the software package EPICURE (Preston et al. 1991) to collapse data into cells that contained person-years of exposure, and numbers of deaths from all causes and from lung cancer. Deaths from lung cancer were defined as those where the underlying cause was coded ICD 162.0 or 162.1. Categories of cells included single calendar years (1959 through 1976), attained age in five-year intervals to age 80, and age in 1959 in five-year intervals. A few lung cancer deaths over age 80 and the associated person-years of follow-up were excluded because of a concern about the quality of death certificate information in this age group. The last four years of follow-up (1977–1980) were excluded because follow-up appeared to be incomplete during this period (Crump et al. 1991; Garshick 1991).

Duration of exposure to diesel exhaust (which was duration of employment) was categorized into 12 intervals (in months: 0–29, 30–44, 45–59, 60–74, 75–89, 90–109, 110–129, 130–149, 150–174, 175–199, 200–224, 225–249, and ≥ 250) with a ramp of linearly increased exposure over the 15 years prior to 1959. Lags of 5 and 10 years were considered. The analysis was limited to men whose job categories in 1959 were classified as (1) clerks, (2) signalmen, (3) engineers and firers, (4) conductors and brakemen, (5) hostlers, and (6) shop workers. These groups were subsequently combined for analysis into three groups consisting of clerks and signalmen (groups 1 and 2), train workers (groups 3 through 5), and shop workers (group 6).

METHODS USED FOR EXPOSURE-RESPONSE ANALYSES

Analyses were based on Poisson regression using the AMFIT module of the software package EPICURE (Preston et al. 1991). Previous analyses (Crump et al. 1991; OEHHA 1998; Crump 1999) also were based on Poisson regression. The variables of employment duration and job category were grouped as described above. Unless noted otherwise, analyses were stratified by attained age (five-year categories) and calendar year (single-year categories). The STRATA command of AMFIT was used to include all interactions among these variables. Duration of employment and measures of cumulative exposure were lagged for five years; alternative analyses using a ten-year lag yielded very similar results. Analyses used deaths in which the underlying cause was lung cancer; analyses that included deaths in which lung cancer was coded as a secondary cause produced similar results.

The results presented are based on the log-linear model (used by OEHHA) in which the relative risk is calculated by

$$RR = e^{\alpha GRP + \beta D},$$

where *GRP* is an indicator variable for groups defined by job category, and *D* is a measure of duration of employment or exposure. Both the estimated coefficients (α and β) and the associated relative risks are presented. Other analyses, based on the linear model (used in many of the analyses conducted by Crump and associates [1991])

$$RR = e^{\alpha GRP}[1 + \beta D],$$

led to conclusions similar to those from the log-linear model. For graphic presentation, relative risks by job category and exposure duration were calculated. Confidence intervals were based on the asymptotic standard errors of α or β. Statistical tests were based on the likelihood ratio statistic. All reported *p* values are two-tailed.

RESULTS OF EXPOSURE-RESPONSE ANALYSES

Other analysts have assigned exposure rates to job categories and multiplied these by various measures of exposure duration. For this reason, the Panel's initial analyses addressed the effects of both duration of employment and job category. For these analyses, three broad job category groups were defined as indicated in Table C.1.

Results of various models are shown in Table C.2. Model 1, which included variables for both job category (*GRP*) and employment duration (*D*0) fit substantially better than a model that included only employment duration ($p < 0.001$; model not shown). The coefficient for *D*0 (expressed per 10 years of employment duration) was negative when the *GRP* variable was not included. In Model 2, which included a separate employment duration coefficient for each of the three job categories, all three coefficients were negative, and this model did not fit significantly better ($p = 0.49$) than Model 1, which used a single employment duration coefficient. For graphic presentation, relative risks for each category defined by duration of employment (0–4, 5–9, 10–14, 15–17, and 18+ years) and job category were calculated with the 0–4-year category for clerks serving as the referent category. These relative risks are shown in Figure C.1.

The next set of analyses explored variables similar to those used by OEHHA in which one constant exposure rate was assigned to clerks and signalmen and another rate to train workers. The exposure rates given in Table 7-2 of the California OEHHA report (1998) were 39 µg/m^3 for clerks and 82 µg/m^3 for train workers. When background exposure (the value for clerks) was subtracted, the result was 0 µg/m^3 for clerks and 43 µg/m^3 for train workers. Because one of the issues of interest was the effect of subtracting background exposure, two exposure variables were defined: *D*1 with no background correction, which equaled 39 µg/m^3 for clerks and 82 µg/m^3 for train workers; and *D*2, with the background exposure subtracted, which equaled 0 µg/m^3 for clerks and 43 µg/m^3 for train workers. Shop workers were excluded from these analyses to be consistent with those of other analysts. (Again, the Panel's analyses were aimed at understanding the data and the factors that influenced risk estimates obtained by others, and not at developing a model for QRA.)

The analyses by OEHHA used exposure measures similar to the *D*2 variable described above; they used exposure intensities of 40, 50, or 80 µg/m^3 for train workers, which were intended to reflect different assumptions regarding baseline exposure concentrations (as described in section 7.2.1.4 of OEHHA 1998). Because the Panel used durations and intensities of exposure that were not identical to those used by the OEHHA, the quantitative risk estimate analyses are not directly comparable. However, the Panel believes that the direction and statistical significance of the effect for the *D*2 variable should be reasonably comparable with the OEHHA results.

Table C.1. Number of Lung Cancer Deaths and Person-Years of Follow-Up by Job Category from Railroad Worker Cohort Data

Job Category	Deaths from Lung Cancer	Person-Years of Follow-Up
Clerks and signalmen	307	220,802
Train workers (including engineers, firemen, conductors, brakemen, and hostlers)	752	462,951
Shop workers	321	190,874

Model 3 included only the *GRP* variable and Models 4 and 5 included only the quantitative cumulative exposure measure *D*1 or *D*2, respectively. Without the *GRP* variable in Models 4 and 5, the coefficients for both *D*1 and *D*2 were positive, but the *p* value for statistical significance was smaller when *D*2 (with background correction) was used (Model 5: $p = 0.005$) than when *D*1 (with no background correction) was used (Model 4: $p = 0.10$). When *GRP* was added (Models 6 and 7), the fit was improved significantly and the coefficients for both *D*1 and *D*2 became negative. In addition, the relative risks for train workers compared with clerks and signalmen became larger than in Model 3, where the variable adjusting for

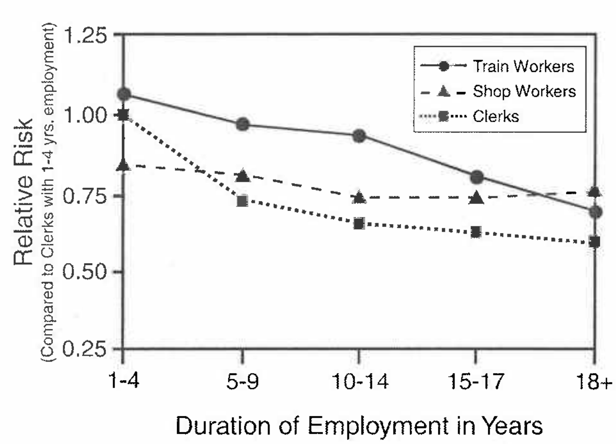

Figure C.1. Panel's analysis depicting consistently elevated risk of lung cancer for train workers compared with clerks for each time period, but decreasing risk by job category over duration of employment.

[a] Coefficient β per 10 years.

[b] Coefficient β per 10^3 ($\mu g/m^3$)-years.

[c] Relative risk e^{β} per 10 years.

[d] Relative risk e^{β} per 10^3 ($\mu g/m^3$)-years.

exposure duration was not included. Analyses based on linear models resulted in a similar pattern, where the sign of the coefficient changed from positive to negative when the *GRP* variable was added to the model.

In Table C.2, the differences in relative risk between train workers and clerks/signalmen, as measured by the parameter α, were assumed not to depend on age or calendar year period. That is, the relative risk of lung cancer for train workers compared with clerks and signalmen was assumed to be the same for all age and calendar year periods.

Further exploration of these data revealed that these relative risks were not constant; risks for train workers increased with calendar year period (after adjustment for age and duration of employment), whereas risks for clerks and signalmen showed little evidence of such an increase. Although the Panel has not explored these differences in detail, they nevertheless illustrate the complexity of these data and the difficulties of providing an adequate summary measure of effect. Calendar year and cumulative exposure are highly correlated, which makes it especially difficult to sort out their separate effects; correlation coefficients (calendar year and cumulative exposure), weighted by person-years, were 0.90 for clerks and signalmen, 0.94 for train workers, and 0.87 for shop workers.

Because of the dependencies noted above, analyses using separate calendar year and age adjustments for each of the three job category groups were also conducted by stratifying on age, calendar year, and *GRP*. Using this approach, the coefficients (with 95% CI) for duration of employment (analogous to those presented in Table C.2, Model 2) were −0.01 (−0.47, 0.44) per 10 years for clerks, −0.55 (−0.84, −0.27) per 10 years for train workers, and −0.09 (−0.46, 0.29) per 10 years for shop workers. The coefficients for *D*1 and *D*2 (analogous to analyses based on Models 6 and 7) were −0.62 (−0.95, −0.28) per 10^3 ($\mu g/m^3$)-years for *D*1, and −1.28 (−1.94, −0.62) per 10^3 ($\mu g/m^3$)-years for *D*2.

Several approaches for adjusting for age and calendar year were explored, including (1) substituting age in 1959 for age at risk, (2) not including interactions of age and calendar year, and (3) treating age as a continuous variable (log-linear) instead of as a categorical variable. Results of fitting these various methods of adjustment to Models 5 and 7 (with *D*2) are shown in Table C.3. With all methods of adjustment, the coefficients from Model 5 (with *D*2 alone) were positive and differed significantly from zero. Also in all cases, these coefficients became negative when a variable measuring differences between train workers and clerks/signalmen (*GRP*) was added (Model 7). However, in some cases (not shown), interaction terms improved the fits of various models, especially if age in 1959 was used instead of age at risk. Also, treating age at risk (or age in 1959) categorically improved the fit over treating these variables continuously.

DISCUSSION

The analyses described above demonstrate that the lung cancer risks for train workers were higher than for clerks and signalmen, and that shop workers had intermediate risks. Within the exposed groups (train workers and shop workers), lung cancer risk decreased with increasing dura-

Table C.3. Estimated Coefficients and 95% Confidence Intervals for Simple Measures of Exposure (*D*2) Based on Different Adjustments to Models 5 and 7 for Age and Calendar Year

Method of Adjusting for Age and Calendar Year[a]	Coefficient β per 10^3 ($\mu g/m^3$)-Years	
	Model 5 Without *GRP* in Model	Model 7 With *GRP* in Model
Age at risk[b], Year, Interaction	0.33 (0.10, 0.57)	−0.47 (−1.01, 0.07)
Age at risk[b], Year	0.32 (0.08, 0.55)	−0.50 (−1.03, 0.04)
Age at risk[c], Year	0.41 (0.17, 0.64)	−0.09 (−0.62, 0.45)
Age in 1959[d], Year, Interaction	0.33 (0.09, 0.56)	−0.49 (−1.04, 0.05)
Age in 1959[d], Year	0.37 (0.14, 0.61)	−0.22 (−0.76, 0.32)
Age in 1959[c], Year	0.41 (0.17, 0.64)	−0.09 (−0.62, 0.45)

[a] "Year" is treated as 18 single-year categories from 1959 through 1976. "Interaction" includes all possible interaction terms for the two variables indicated.

[b] "Age at risk" is treated as 8 five-year categories 40–44, 45–49, . . . , 75–79.

[c] Age is treated as a continuous variable.

[d] "Age in 1959" is treated as 5 five-year categories 40–44, 45–49, . . . , 60–64.

tion of employment, although this decrease was statistically significant only for the train workers. If exposure to diesel exhaust increased the risk of lung cancer in a monotonic fashion, such decreases would not be expected.

Simple measures of exposure, determined by multiplying duration of employment by exposure intensities assumed to be constant for the clerks/signalmen and train worker groups, were also analyzed. With no adjustment for job category, a positive slope was obtained, which was statistically significant when zero intensity was assumed for the clerks and signalmen group. To clarify the extent to which this positive response was due to the difference in baseline risks for train workers compared with clerks and signalmen, the variable *GRP* to measure this difference was included in the model. When this was done, the direction of association with exposure became negative; this result reflects entirely the decreasing association with increasing employment duration for train workers, and demonstrates that the positive exposure-response relation obtained with Models 4 and 5 was entirely due to the baseline differences between the two job categories.

The exposure measure defined for Model 5 above was categorized as > 0–465, 466–626, and 627 or more ($\mu g/m^3$)-years. Compared with the 0 category, the relative risks (and 95% CIs) are 1.4 (1.2, 1.7), 1.3 (1.1, 1.6), and 1.1 (0.9, 1.3), respectively. The clerks and signalmen comprised the 0 category, and the positive exposure categories were equivalent to duration of employment categories for train workers. For the train workers, the cut points 466 and 627 ($\mu g/m^3$)-years correspond to 10.8 and 14.6 years (or 130 and 175 months in the original categorization of the data).

The exposure-response function indicated by the relative risks noted in the previous paragraph and the decrease in risk with increasing duration of employment shown in Figure C.1 is not consistent with a positively increasing association between cumulative exposure to diesel exhaust and lung cancer risk. Even if the estimated exposure intensities were incorrect, a positive trend with duration of employment would be expected for the exposed groups (including train workers) if lung cancer risk increased consistently with increasing cumulative exposure. Furthermore, if the difference between train workers and clerks/signalmen were primarily due to differences in exposure, one would expect the relative risk for train workers, compared with clerks and signalmen, to be smaller or even eliminated after adjusting for exposure. However, adjusting for exposure increased this relative risk, as shown with Models 6 and 7 (compared with Model 3) in Table C.2.

The above analyses consider the ramp pattern of exposure (see Figure 7 in the chapter Summary of Railroad Worker and Teamster Studies); however, analyses using the roof pattern of exposure produced similar results. For Models 4 and 5 using the roof pattern, the slopes for cumulative exposure *D*1 and *D*2 increased to 0.64 and 0.97, respectively. When *GRP* was included, as in Models 6 and 7, the slopes for *D*1 and *D*2 became negative (–0.82 and –0.86, respectively). Thus, the coefficients for cumulative exposure using the roof pattern responded in the very same manner as they did using the ramp pattern, changing from positive to negative when the variable for job category (*GRP*) was included.

The OEHHA also applied a multistage model to the data to make quantitative risk estimates. This involved assigning exposure concentrations to job categories for modeling. As a correction for background exposure, the clerks and signalmen were given values of zero exposure rate as was done in Model 5 of Table C.2. The OEHHA reported a positive dose-response relation, as is also shown with Model 5. This multistage approach is likely to have the same difficulties with cumulative exposure as were pointed out in the discussion of Models 5 and 7.

The differences between train workers and clerks/signalmen and the negative association with employment duration within job category (especially the train workers) indicate a strong likelihood of bias due to unmeasured variables, such as smoking, or to differential follow-up among the groups being compared, or to both. The reasons for these biases are not known, but it is the Panel's opinion that their probable presence makes these data unsuitable for QRA.

In addition, the strong correlation between calendar year and duration of employment makes it very difficult to sort out the separate effects of these variables. In a study with excellent data on exposure and on other risk factors for lung cancer, this might be possible. However, this study did not include data that clearly distinguish exposure rates among workers, and did not indicate changes in these rates over time for individual workers. Data on potential confounders such as smoking were also unavailable. Although the railroad worker data do not show an increasing relation between exposure to diesel exhaust and risk of lung cancer, the possibility that strong biases in these data have masked a true association cannot be ruled out. It is also possible that the follow-up period has been too short for effects to become evident, or that the true exposure-response relation in these data is nonmonotonic. With these limited data, it is not possible to determine whether the exposure-response relation is, in fact, nonmonotonic, or the result of bias in the data.

Model 5 is similar to the model used as the basis for the California OEHHA's risk assessment (1998). This model does not fit the data, as was demonstrated by the strong improvement in fit when the variable reflecting the difference between train workers and clerks/signalmen (*GRP*) was added (Model 7). Analyses using Model 5 differ from OEHHA's analyses in that (1) the employment duration measure OEHHA used did not take into account the portion of the year (months) workers were employed, and (2) the methods used to adjust for age and calendar year period were slightly different. Although these differences could affect the quantitative estimates, it seems unlikely that they would affect qualitative conclusions.

Crump (Crump et al. 1991; Crump 1999) also has conducted many analyses of the railroad worker data, and has investigated duration of employment as well as more complex measures of exposure than the Panel used in its analyses. However, Crump's results are likely to reflect the negative association of duration of employment within job categories. Crump has noted that the OEHHA positive slope is driven by the difference between train workers and clerks/signalmen (Crump 1999), and the Panel's analyses confirm this. The Panel used results of the analyses with and without terms for job category, in an attempt to clarify the roles of job category (as a measure of exposure intensity) and employment duration, and to understand to a greater extent than in previous discussions of these analyses the differences in results obtained by OEHHA and by Crump and colleagues.

Methods to adjust for age and calendar year, particularly regarding the choice between attained age or birth cohort (equivalent to age in 1959), have received considerable discussion. Because any two of the variables (attained age, birth cohort, and calendar year) determine the third, this choice in itself should not matter provided that an interaction among the variables is allowed. However, different results might arise because of the number and definition of the categories used, or because interactions were not included in the model. The California OEHHA (1998) has conducted analyses, applying many different treatments of age and calendar year, with little evidence of an important impact on results. The Panel's investigation of this issue confirms this conclusion, in that analyses were not greatly affected by the method of adjusting for age and calendar year.

ACKNOWLEDGMENTS

The Panel greatly appreciates the helpful cooperation of Drs. Eric Garshick, Kenny Crump, and Stanley Dawson in providing data and other information regarding their analyses of the railroad worker data.

Appendix D. Potential Impact of Control Selection Bias

The Panel, having raised the possibility that bias could have been introduced during the selection of control groups for the case-control studies by Garshick and colleagues (1987) and Steenland and coworkers (1990), offers hypothetical examples showing the potential for bias in case-control studies with deaths from "other causes." "Other causes" in these examples are depicted as CVD mortality because it is the leading cause of death among men; the problems arise because CVD often is associated strongly with smoking as well as with choice of occupation. The Panel presents five different scenarios concerning the association between (1) diesel exhaust and lung cancer, (2) diesel exhaust and "other" causes of death, (3) smoking and lung cancer, (4) smoking and the "other" causes of death, and (5) diesel exhaust, smoking, and lung cancer. These examples demonstrate that case-control studies using "other" causes of death as the control group have the potential to produce misleading results.

In all the examples it is assumed that:

- smoking has a strong, positive effect on lung cancer mortality risk: RR = 7.00; and
- smoking has a weaker, positive effect on CVD mortality risk: RR = 2.00.

The examples differ by:

- whether exposure to diesel exhaust has a positive effect (RR > 1.00) or no effect (RR = 1.00) on lung cancer risk;
- whether smoking is correlated with diesel exhaust exposure, with 65%, 50%, or 35% of smokers in the exposed group; and
- whether CVD risk is increased (RR = 1.54) or decreased (RR = 0.65) among exposed persons, within strata of cigarette smoking.

In each example, a cohort study that lacked information on smoking would provide a biased estimate of the crude relative risk (in the row in each section of the tables labeled "Total"). A case-control study with CVD deaths as controls and with information on smoking, as conducted by Garshick and colleagues (1987) and Steenland and coworkers (1990), would provide estimates of the crude and stratum-specific relative risks in the last column of each table.

Table D.1 includes data for the first three examples. In all three, exposure to diesel exhaust *has no effect on* lung cancer, and exposed persons are *at lower risk* of CVD than unexposed persons within strata of smoking. Smoking is associated with diesel exhaust in a different direction for each example.

In the first example (section A of Table D.1), smoking is positively associated with diesel exposure. A cohort study of this population would report a crude RR = 1.58, which would be due entirely to confounding by smoking. A case-control study with CVD deaths for controls would report a crude estimate of RR = 1.99, which would appear to be due only partially to confounding by smoking. The smoking-adjusted estimate from the case-control study would be RR = 1.54, very similar to the unadjusted estimate of 1.58 from the cohort study. The adjustment for smoking in the case-control study would be falsely reassuring because of control selection bias.

In the second example (section B of Table D.1), smoking is inversely associated with exposure. If the case-control study only were performed, as in the case of the study by Steenland and colleagues, the implausible RR = 0.63 in the cohort, unadjusted for smoking, would never be seen. The case-control study would find a weak association between exposure and lung cancer (RR = 1.19) before adjusting for smoking, which would become stronger (RR = 1.54) when smoking is controlled. However, the scenario assumes that diesel exposure conditional on smoking status has no effect on lung cancer (RR = 1.00).

In the third example (section C of Table D.1), smoking is unassociated with exposure. As in the second example, suppose that only the case-control study is conducted. Control selection bias resulting from the use of CVD controls would produce an upwardly biased estimate of RR = 1.54, whether or not smoking is controlled for in the analysis.

Table D.2 includes data for the fourth and fifth examples. For both hypotheses, exposure to diesel exhaust *increases* lung cancer risk, and exposed persons are *at higher risk* of CVD than unexposed persons within the strata of smoking. The association of smoking and diesel

[a] Results from a cohort study without smoking information and from a case-control study with CVD controls and smoking information are shown in bold.

exhaust is assumed to go in opposite directions for each example.

In the fourth example (section A of Table D.2), smoking is positively associated with exposure. The cohort study with no smoking information gives too high an estimate (RR = 3.16) of the actual effect of exposure to diesel exhaust on lung cancer risk (RR = 2.00). Because of control selection bias, the estimates from the case-control study are too low, regardless of whether they are computed with (RR = 1.30) or without (RR = 1.68) adjustment for smoking.

In the fifth example (section B of Table D.2), smoking is inversely associated with exposure. As in the fourth example, the unadjusted result of the cohort study and the unadjusted and adjusted results of the case-control study underestimate the effect of exposure on lung cancer risk.

These examples show that a severely distorted estimate of the association between exposure to diesel exhaust and lung cancer, and a severely distorted picture of the direction and degree of confounding by cigarette smoking, can come from case-control studies in which the controls are a collection of "other deaths" composed largely of CVD deaths.

Table D.2. Hypothetical Examples in Which Exposure to Diesel Exhaust Increases Lung Cancer Risk, Exposed Persons Are at Higher Risk of Cardiovascular Disease Than Unexposed Persons Within Strata of Smoking, and the Association Between Smoking and Exposure Changes

			Risk		Cases		Relative Risk of Lung Cancer[a]	
Smoking	Diesel Exposure	Number of Persons	Lung Cancer	Cardio-vascular Disease	Lung Cancer	Cardio-vascular Disease	Cohort	Case Control
A. Smoking Is Positively Associated with Exposure								
Yes	Yes	65,000	0.00280	0.02000	182	1,300	2.00	**1.30**
	No	35,000	0.00140	0.01300	49	455	1.	1.
No	Yes	35,000	0.00040	0.01000	14	350	2.00	**1.30**
	No	65,000	0.00020	0.00650	13	423	1.	1.
Total	Yes	100,000	0.00196		196	1,650	**3.16**	**1.68**
	No	100,000	0.00062		62	878	1.	1.
B. Smoking is Inversely Associated with Exposure								
Yes	Yes	35,000	0.00280	0.02000	98	700	2.00	**1.30**
	No	65,000	0.00140	0.01300	91	845	1.	1.
No	Yes	65,000	0.00040	0.01000	26	650	2.00	**1.30**
	No	35,000	0.00020	0.00650	7	228	1.	1.
Total	Yes	100,000	0.00124		124	1,350	**1.27**	**1.01**
	No	100,000	0.00098		98	1,073	1.	1.

[a] Results from a cohort study without smoking information and from a case-control study with CVD controls and smoking information are shown in bold.

Carcinogenicity of diesel-engine and gasoline-engine exhausts and some nitroarenes

In June, 2012, 24 experts from seven countries met at the International Agency for Research on Cancer (IARC; Lyon, France) to assess the carcinogenicity of diesel and gasoline engine exhausts, and some nitroarenes. These assessments will be published as Volume 105 of the IARC Monographs.[1]

Diesel engines are used for on-road and non-road transport (eg, trains, ships) and (heavy) equipment in various industrial sectors (eg, mining, construction), and in electricity generators, particularly in developing countries. Gasoline engines are used for cars and hand-held equipment (eg, chainsaws).

Emissions from these engines are complex, with varying composition. The gas phase consists of carbon monoxide, nitrogen oxides, and volatile organic compounds such as benzene and formaldehyde. Particles consist of elemental and organic carbon, ash, sulfate, and metals. Polycyclic aromatic hydrocarbons and nitroarenes are distributed over the gas and the particle phase. The qualitative and quantitative composition of exhausts depends on the fuel, the type and age of the engine, the state of its tuning and maintenance, the emission control system, and pattern of use. Diesel-engine exhaust from engines with no or limited emission controls contains more particulate matter.[2]

In the past two decades, progressively tighter emission standards for on-road vehicles, introduced in North America, Europe, and elsewhere, have triggered advances in diesel technology that resulted in lower emission of particulate matter, nitrogen oxides, and hydrocarbons. Emission standards in non-road applications are lagging and therefore are still largely uncontrolled today. Moreover, in many less developed countries standards are not in place for both on-road and non-road use of diesel and gasoline engines.

The most influential epidemiological studies assessing cancer risks associated with diesel-engine exhausts investigated occupational exposure among non-metal miners, railroad workers, and workers in the trucking industry. The US miners study included a cohort analysis[3] and a nested case–control analysis that was adjusted for tobacco smoking.[4] Both showed positive trends in lung cancer risk with increasing exposure to diesel exhaust, as quantified via estimated elemental carbon as a proxy of exposure. Trends were significant in the nested case–control study, with a 2–3-fold increased risk in the highest categories of cumulative or average exposure. This study provides some of the strongest evidence of an association between exposure to diesel-engine exhaust and lung cancer since there were few potential confounding exposures in these underground mines, and high diesel exposures were well documented in current surveys.

In another US study,[5] a 40% increased risk for lung cancer was observed in railroad workers exposed to diesel exhaust compared with individuals exposed to low levels of or no emissions. Indirect adjustment for smoking suggested that differences in smoking could not have influenced this excess risk substantially. This study was later extended by estimating diesel exposure on the basis of work history and history of dieselisation of different railroads, and showed a significantly increased risk for exposed workers of 70–80%; risk increased with duration of exposure but not with cumulative exposure.[6]

A large cohort study in the US trucking industry[7] reported a 15–40% increased lung cancer risk in drivers and dockworkers with regular exposure to diesel exhaust. There was a significant trend of increasing risks with longer duration of employment, with 20 years of employment roughly doubling the risk after adjusting for tobacco smoking. When this study was extended with an exposure assessment involving contemporary measurements and exposure reconstruction on the basis of elemental carbon, positive trends were observed for cumulative but not average exposure. These trends were more pronounced when adjustment for duration of work was included.[8]

The findings of these cohort studies were supported by those in other occupational groups and by case–control studies including various occupations involving exposure to diesel-engine exhaust. A positive exposure–response relationship was found in several studies from Europe and the USA, many of which were adjusted for tobacco smoking. Most notably, a pooled analysis of 11 population-based case–control studies from Europe and Canada showed a smoking-adjusted increased risk for lung cancer after exposure to diesel engine exhaust, which was assessed by a job exposure matrix, and a positive dose response in terms of both a cumulative exposure index and duration of exposure.[9]

These epidemiological studies support a causal association between exposure to diesel-engine exhaust and lung cancer. An increased risk for bladder cancer was also noted in many but not all available case–control studies. However, such risks were not observed in cohort studies. The Working Group concluded that there was “sufficient evidence” in humans for the carcinogenicity of diesel-engine exhaust.

The diesel-engine exhausts and their extracts used in carcinogenicity studies with experimental animals were generated from fuels and diesel engines produced before 2000. The studies were considered by type of

Conflicts of interest

DBK has received research funding from Caterpillar and from British Petroleum. MvT has received research funding from Statoil, CONCAWE, and CEFIC. JG has received research funding from CONCAWE. DG is the President of the Health Effects Institute (the Institute's funding comes in equal part from the US Environmental Protection Agency and the makers of motor vehicles for sale in the USA). TH is an employee of Navistar (manufacturer of diesel trucks and engines). TLL served as a consultant to the diesel industry through Cambridge Environmental. RM serves as a consultant for the Engine Manufacturers Association, Navistar International, Cummins Engine Company, Shell Exploration and Production Company, Union Pacific, and the American Petroleum Institute. PM is a member of the Scientific Advisory Group of European Research Group on Environment and Health in the Transport Sector. DP holds stock in Daimler-Benz AG and was employed until 2008 by BASF. JCW is Vice President and Chief Technical Officer of Cummins, and holds stock and patents. SM holds stock in BHP Billiton Limited. All other Working Group members, specialists, representatives, and secretariat declare that they have no conflicts of interest.

*Strong mechanistic evidence contributed to the overall evaluation.

***Table:* Evaluation of some nitroarenes**

exposure: whole diesel-engine exhaust; gas-phase diesel-engine exhaust (with particles removed); and extracts of diesel-engine exhaust particles. Whole diesel-engine exhaust caused an increased incidence of lung tumours in rats.[10] Diesel-engine exhaust particles instilled intratracheally caused benign and malignant lung tumours in rats,[11] and the particle extracts also caused lung carcinomas in rats and sarcomas at the injection site in mice.[12,13] Gas-phase diesel-engine exhaust did not increase incidence of respiratory tumours in any species tested. The Working Group concluded that there was "sufficient evidence" in experimental animals for the carcinogenicity of whole diesel-engine exhaust, of diesel-engine exhaust particles and of extracts of diesel-engine exhaust particles.

Diesel-engine exhaust, diesel-exhaust particles, diesel-exhaust condensates, and organic solvent extracts of diesel-engine exhaust particles induced, in vitro and in vivo, various forms of DNA damage, including bulky adducts, oxidative damage, strand breaks, unscheduled synthesis, mutations, sister chromatid exchange, morphological cell transformation in mammalian cells, and mutations in bacteria.[14] Increased expression of genes involved in xeno-biotic metabolism, oxidative stress, inflammation, antioxidant response, apoptosis, and cell cycle in mammalian cells was observed.

Positive genotoxicity biomarkers of exposure and effect were also observed in humans exposed to diesel engine exhaust. The Working Group concluded that there is "strong evidence" for the ability of whole diesel-engine exhaust to induce cancer in humans through genotoxicity.

Gasoline exhaust and cancer risk was investigated in only a few epidemiological studies and, because of the difficulty to separate effect of diesel and gasoline exhaust, evidence for carcinogenicity was evaluated as "inadequate".

The Working Group considered the animal carcinogenicity studies of gasoline-engine exhaust by type of exposure: whole gasoline-engine exhaust; and extracts of gasoline-engine exhaust condensate. Organic extracts of gasoline engine-exhaust condensate induced a significant increase in lung carcinomas and papillomas of the skin in mice.[15] In rats, the gasoline-exhaust condensate induced a significant increase in lung carcinomas.[16] The Working Group concluded that there was "sufficient evidence" in experimental animals for the carcinogenicity of condensates of gasoline-engine exhaust.

Gasoline-engine exhaust induced chromosomal damage in mice, and changes in gene expression in rat lung that involved pathways related to xenobiotic metabolism and inflammation. In mammalian cells, gasoline-engine exhaust particles and organic extracts thereof induce DNA adducts, DNA strand breaks, oxidative DNA damage, chromosomal aberrations, and morphological cell transformation, as well as gene mutations in bacteria. In mammalian cells, extracts of gasoline-exhaust engine particles altered expression of genes involved in inflammation, xenobiotic metabolism, tumour progression, and cell cycle. The gaseous phase of gasoline-engine exhaust was mutagenic to bacteria. The Working Group concluded that there is "strong evidence" for a genotoxic mechanism for the carcinogenicity of organic solvent extracts of particles from gasoline engine exhaust.

In conclusion, the Working Group classified diesel engine exhaust as "carcinogenic to humans" (Group 1) and gasoline engine exhaust as "possibly carcinogenic to humans" (Group 2B).

Evaluations for ten nitroarenes, all of which have been detected in diesel-engine exhaust, are shown in the table. Biomonitoring studies have shown that workers and the general population are exposed to these substances.[17–19] All the nitro-arenes were genotoxic to various extents in different assays. The Working Group reaffirmed the Group 2B classification of seven. Strong evidence for genotoxicity led to an upgrade of 3-nitrobenzanthrone to Group 2B, and similar findings in human cells led to an upgrade of 1-nitropyrene and 6-nitrochrysene to Group 2A.

Increasing epidemiological evidence has established an association between a host of adverse health effects and exposure to ambient particulate matter (PM) and co-pollutants, especially those emitted from motor vehicles. Although PM and their co-pollutants dispersion profiles near the open freeway have been extensively characterized by means of both experimental measurements and numerical simulations in recent years, such investigations near freeways with roadside barriers have not been well documented in the literature. A few previous studies suggested that the presence of roadside structures, such as noise barriers and vegetation, may impact the decay of pollutant concentrations downwind of the freeway by limiting the initial dispersion of traffic emissions and increasing their vertical mixing due to the upward deflection of airflow. Since the noise barriers are now common roadside features of the freeways, particularly those running through populated urban areas, it is pertinent to investigate the impact of their presence on the particles and co-pollutants concentrations in areas adjacent to busy roadways. This study investigated two highly trafficked freeways (I-710 and I-5) in Southern California, with two sampling sites for each freeway, one with and the other without the roadside noise barriers. Particle size distributions and co-pollutants concentrations were measured in the immediate proximity of freeways and at different distances downwind of the freeways. The results showed the formation of a "concentration deficit" zone in the immediate vicinity of the freeway with the presence of roadside noise barrier, followed by a surge of pollutant concentrations further downwind at 80–100 m away from freeway. The particle and co-pollutants concentrations reach background levels at farther distances of 250–400 m compared to 150–200 m at the sites without roadside noise barriers.

1. Introduction

In recent years, several toxicological studies have reported the ability of particulate matter (PM) to generate reactive oxygen species in biological systems (Sagai et al., 2000; Donaldson et al., 2002; Xia et al., 2004) and these pro-oxidant species are intimately linked to the genesis of pulmonary (Li et al., 2009) and cardiovascular (Delfino et al., 2005) injury, and even neurodegenerative disorders (Campbell, 2004; Peters et al., 2006). In urban areas, the primary source of ambient PM and their co-pollutants come from motor vehicles and traffic-induced emissions (Ning and Sioutas, 2010), which raises serious health concerns for the part of the population who live and/or work in the communities nearby busy roadways or spend several hours daily commuting. Several epidemiological studies have reported a strong and positive association between a community's proximity to highly trafficked roadways and the risk of adverse health effects among the population in the community, including asthma and other respiratory diseases (Delfino, 2002; McConnell et al., 2006), birth and developmental defects (Ritz and Yu, 1999; Wilhelm and Ritz, 2003), cardiovascular diseases (Peters et al., 2004; Delfino et al., 2005) and childhood cancer such as leukemia (Harrison et al., 1999; Pearson et al., 2000).

Particle and gaseous pollutants dispersion profiles near open freeways have been well documented by means of both experimental measurements and numerical simulations in recent years. One of the first such attempts was undertaken by Zhu et al. (2002a, b) in the vicinity of Interstate 405 and 710 freeways in Southern California. It was observed that the particle number and CO concentrations decreased exponentially, and particle size distributions shifted towards larger particle diameters as the aerosols were transported away from freeway, which the authors attributed

doi:10.1016/j.atmosenv.2010.05.033

to particle coagulation and turbulent dispersion. Similar experimental investigations were also carried out in other cities around the world (Gramotnev and Ristovski, 2004; Zhu et al., 2009). On the other hand, several modeling studies have attempted to explain the particles evolution near roadways (Jacobson and Seinfeld, 2004; Zhang et al., 2004; Jacobson et al., 2005). Zhang et al. (2004) used a multi-component aerosol dynamic model to fit the measurement data from Zhu et al. (2002a) studies and demonstrated that condensation/evaporation and dilution were the major mechanisms in altering aerosol size distribution downwind the freeway. A recent study by Jacobson et al. (2005) suggested that evaporation causes smaller semi-volatile particles to shrink in size and thus enhanced their coagulation rate, which played an important role in the near-source evolution of particle size distribution.

Although these experimental and modeling studies have characterized the roadside particle and co-pollutants dispersion profiles quite extensively, the roadways under investigation were often open -field without considering any roadside obstacles. These roadside structures, such as noise barrier, vegetation and buildings, may affect the characterization of pollutants decay profiles downwind of roadway by limiting or blocking the initial dispersion of traffic-induced emissions from roadway and increasing their vertical mixing due to the upward deflection of airflow caused by the obstacles (Holscher et al., 1993; Heist et al., 2009). Given that the noise barriers, built to reduce noise levels in areas nearby roadways, are common roadside features of highly trafficked freeways, particularly those running through densely populated areas, it is pertinent to investigate the effect of their roadside presence on particles and co-pollutants concentration levels in areas adjacent to the busy roadways.

Few recent studies demonstrated that a recirculation cavity, consisting of well-mixed and substantially lower concentrations of pollutants, exists in the lee of the roadside barrier (Holscher et al., 1993; Bowker et al., 2007; Baldauf et al., 2008b). This "concentration deficit zone" can extend from 3 to more than 20 times the barrier heights depending on the meteorological conditions and barrier configurations (Baldauf et al., 2008b; Heist et al., 2009). Modeling studies also suggested the existence of a "hot" zone at further distances downwind of the recirculation wake region, where the pollutant concentrations are higher than at an equivalent distance in an open area without barrier, due to the vertical elevation of roadway emissions source by the barrier and the subsequent reattachment of airflow further downwind (Bowker et al., 2007). Based on the previous investigations, the present study employed an intensive sampling campaign and examined the impact of the roadside noise barrier on the dispersion profiles of particles and co-pollutants from freeway emissions. In this study, we selected two major freeways in Southern California (I-710 and I-5) with different traffic fleet compositions. For each freeway, we have selected two sampling sites featured with- and without roadside noise barrier, respectively. The particle size distribution and co-pollutants concentrations were measured at different distances downwind of the freeways to investigate the effect of noise barrier on the decay of their concentrations and the evolution of particle size distributions from traffic-induced emissions. The results of the current study, based on real-world experimental measurement, provide direct evidence that the existence of roadside noise barrier dramatically alters the dynamics of particle and co-pollutants dispersion and the spatial distribution of pollutants concentrations in the areas nearby the freeways.

2. Experimental methodology

2.1. Site locations

An intensive summer sampling campaign has been carried out in the present study during June–July, 2009 to investigate the impact of roadside noise barrier on the dispersion profile of particles and co-pollutants emitted from freeways. Two highly trafficked freeways in greater Los Angeles area (I-710 and I-5) were selected, with two sampling sites (one with roadside noise barrier and the other without) located along the span of each freeway. At each of the four sites, a stationary sampling station was set up located in the immediate proximity of the freeways to characterize the freeway emissions, while a mobile platform was deployed along the trajectories downwind of the traffic emissions from freeway to collect ambient data at varying distances. Fig. 1 (a, b, c and d) shows the location of the four sampling sites and the route of the mobile platform at the downwind area of the selected freeways.

The I-710 non-noise barrier site (Fig. 1a) is located in the stretch of the freeway in Downey, CA. Any major roadway in the upwind direction of the stationary sampling station was at distance greater than 1 km. The inlet of the sampling instruments was extended to as close as 2 m from the freeway edge. The location of the station and the route of the mobile platform are also highlighted in Fig. 1a. I-710 noise barrier site (Fig. 1c) was located 2 km north of the non-noise barrier site in a residential neighborhood in Bell Gardens, CA, with no major roadways, other than the freeway, upwind to about 1 km from the stationary sampling station. The station was set up on the freeway curbside and the inlet reached over the noise barrier into the freeway with a short distance of 2 m from the freeway edge. The barrier was 3.7 m in height as measured above the adjacent surface road next to the noise barrier and extended more than few hundred meters from the site in both north and south bound sections along the freeway. The mobile platform route downwind of the freeway is identified in the Fig. 1c.

The I-5 non-noise barrier site (Fig. 1b) was located in the stretch of the freeway near La Mirada, CA. There were no other major roadways upwind of the sampling site other than the freeway and the vicinity of the sampling site is mainly comprised of office buildings without immediate industrial sources nearby. The stationary sampling location was set next to the freeway curb with the inlet reaching within 0.5 m to the edge. The noise barrier site in I-5 (Fig. 1d) was located in a residential neighborhood, with the roadside noise barrier extending for hundreds meters along the freeway north of the sampling location. The height of the noise barrier at the site was 5.2 m as measured above the adjacent surface road next to the noise barrier. The inlet of the stationary sampling station was extended over the barrier and reached into the freeway zone with offset about 4 m from the edge of the freeway.

2.2. Instrumentation

Two sampling instrument sets were deployed simultaneously, one at the stationary sampling station and the other in the mobile platform. A list of the instruments at both sampling stations with their data resolution is shown in Table 1. The stationary station set up included a Scanning Mobility Particle Sizer (Model 3080, TSI) configured to measure the particle size distribution in the size range of 10–225 nm. Particle-bound black carbon (BC) and co-pollutants of carbon monoxide (CO) and nitrogen dioxide (NO_2) concentrations in the immediate proximity of freeway were also measured at the station. A camera was set up on top of the sampling station to capture the traffic on the freeway and an ultrasonic anemometer was set up at a height of 4 m above the freeway road surface at all of the four sampling sites to collect meteorological data. For the noise barrier sites, the probe was placed upwind of the barrier to avoid possible interferences of the barrier on the measurements.

The mobile platform is a 1998 electric Toyota RAV4 SUV equipped with various on board monitoring instruments. The same vehicle has been used in many previous studies (Westerdahl et al., 2005; Fruin et al., 2008; Kozawa et al., 2008) in Southern California.

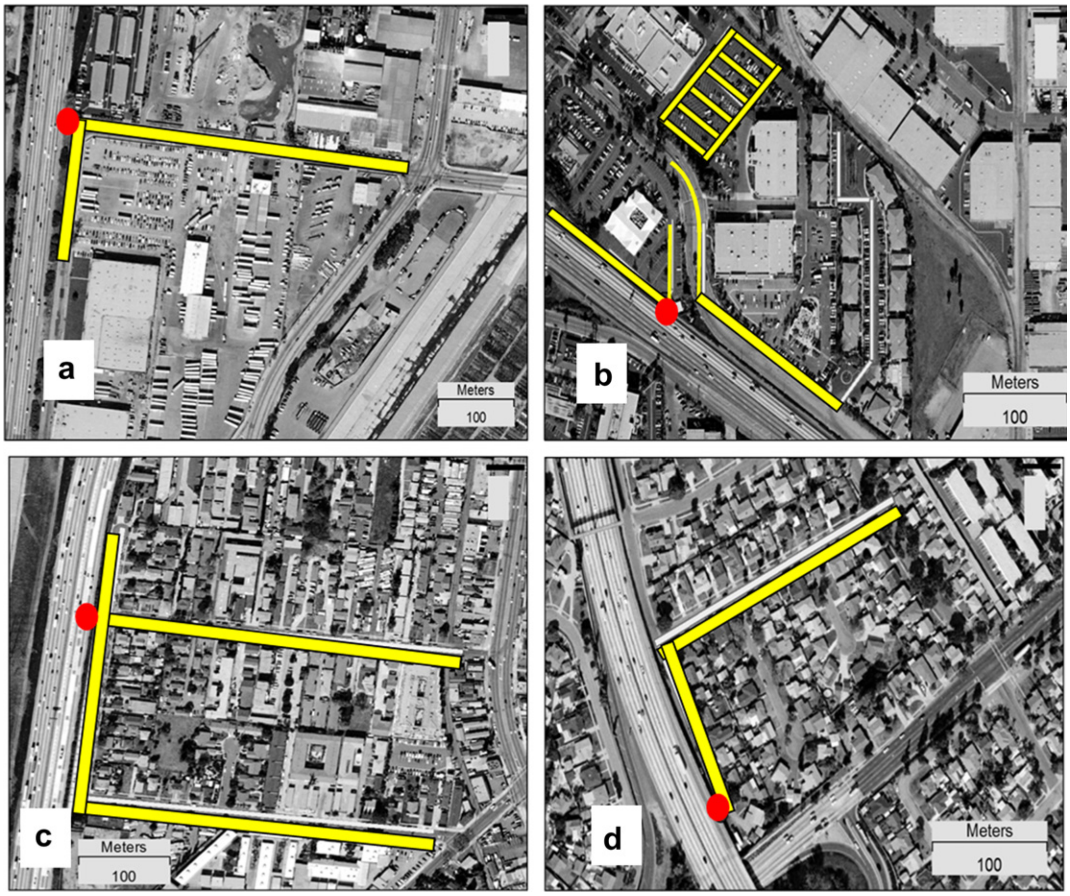

Fig. 1. Location of the sampling sites: (a) I-710 without roadside barrier; (b) I-5 without roadside barrier; (c) I-710 with roadside barrier; (d) I-5 with roadside barrier. Note: Red dot represents the stationary sampling station; the yellow lines represent the route of the mobile platform downwind of the freeway.

The sampling inlet consists of a 6-inch diameter galvanized steel duct, located 1.5 m above the roadway in the rear passenger space of the vehicle. The particle size distributions data (6–523 nm) were collected using aFast Mobility Particle Sizer(Model 3091, TSI). Particle-bound black carbon and co-pollutants (CO, NO_2) concentrations were measured simultaneously to calculate their downwind concentration ratios. A GPS unit was used to record the geocoded data of the mobile platform to derive its downwind distance from the freeway. The mobile platform was also equipped with an on board camera to distinguish a time when the measurements were impacted by a passing vehicle near the mobile platform.

Quality assurance measures, including flow and zero checks of all instruments, and regular calibration of gaseous pollutant monitoring instruments, were carried out before and after the sampling campaign. The side-by-side test results showed that two sets of continuous monitoring instruments for CO, NO_2 and BC deployed in the stationary site and in the mobile platform reported values within 5% of each other. All the instruments ran on synchronized time at both stationary station and the mobile platform. The two instrument sets were run side-by-side overnight at the beginning and end of each sampling period for the four sampling sites to assess the systematic uncertainty due to the difference of monitoring instruments and to inspect the time lag (a consequence of different flow rates, inlet lengths, and instrument response time) between the actual sampling and the reported time.

2.3. Data processing

All data from the stationary sampling station were downloaded and exported using proprietary software and data from the mobile platform were exported to a custom database for all instruments. Data used for data analysis (specified in Table 2) were chosen from the sampling time periods with the measured wind direction $\pm 45°$ from that perpendicular to the freeway, placing the sampling

[a] The traffic volume and composition data were obtained from California Freeway Performance Measurement System (PeMS) by CalTrans.
[b] Wind directions perpendicular to roadway are 270 and 225° true N for I-710 and I-5 sites, respectively.

locations of the mobile platform in the direct downwind vicinity of the selected roadway region. The time periods that were influenced by non-freeway emissions (i.e. a truck passing by the mobile platform) were excluded from the data analysis. GPS tracking data were exported and converted to determine the mobile platform's perpendicular downwind distance to the freeway. The particle size distribution and other pollutants concentration data at various downwind distances were segregated into several distance ranges, and the distance values presented in the *X*-axis of the figures hereafter represent the midpoint of each distance range. Additional information is listed in detail in the Supporting information file. The concentration ratios of NO_2, CO, and BC at different downwind distances of the freeway were determined by normalizing the downwind data from mobile platform with their corresponding data collected from the stationary sampling station. For CO, the data for the I-5 freeway at the stationary station were not available due to a malfunctioning instrument, therefore absolute concentrations are presented. The particle size distribution data were further segregated into several size groups to derive their respective number and mass concentrations at various distances. The particle mass concentrations were determined by their corresponding particle volume concentrations and particle density of 1.2 g cm^{-3} (Geller et al., 2006).

3. Results and discussion

3.1. Overview of the sampling campaign

Table 2 shows the summary of the meteorological conditions, traffic volumes and average freeway pollutants concentrations measured in the immediate proximity of the freeways during the sampling campaign. Similar temperature and humidity conditions were observed among different sites. The average wind directions were in the range of 225 and 233° to the north, placing the selected sampling sites directly downwind of the freeways, and the mean wind speed was in the range of 0.9–3.1 m s^{-1}. Traffic data were obtained from the California Department of Transportation 'California Freeway Performance Measurement System' (PeMS) corresponding to the sampling periods, and the vehicles on both north and south bound directions have been counted. The total traffic flows measured on I-710 and I-5 were ~12 200 and ~8500 vehicles $hour^{-1}$, respectively, with a lower truck flow, e.g. heavy duty diesel vehicles, on I-710 (~500 trucks $hour^{-1}$) than I-5 (~640 trucks $hour^{-1}$). For the two sites at the same freeway, the traffic volume and truck composition were very consistent. The similarity of their meteorological and traffic conditions allows for a direct comparison between the results of the barrier and non-barrier sites.

The average CO concentrations were 1.5 ± 0.4 and 1.4 ± 0.1 ppm at the two sites in the immediate proximity of I-170 freeway. Their concentrations near I-5 were not reported in Table 2 due to a malfunctioning of the instrument. The BC concentrations measured in the two sites at I-710 freeway were 11.0 ± 6.3 and 11.6 ± 1.4 μg m^{-3}, comparable to 10.6 ± 4.2 and 9.5 ± 1.5 μg m^{-3} measured at I-5. In comparison to the previous measurement on I-710 freeway (Westerdahl et al., 2005), in which the BC and CO concentrations were 12 μg m^{-3} and 1.9 ppm as measured while driving on the same freeways using a mobile platform, the results from both studies were very consistent. The average particle number concentrations measured by SMPS (10–225 nm) at both I-710 sites (1.2 ± 0.5e5 and 1.1 ± 0.2e5 particles cm^{-3}) are higher than those at I-5 sites (8.0 ± 3.4e4 and 7.5 ± 2.4e4 particles cm^{-3}), due to the higher traffic volume on I-710.

3.2. Evolution of particle size distributions downwind of freeway

Fig. 2a and b show the average particle size distributions at various distances downwind of I-710 (20, 40, 80, 200 and 450 m) and I-5 (20, 40, 90, 120, 400 m) freeways without roadside noise barriers as measured by FMPS (6–523 nm). The size distributions

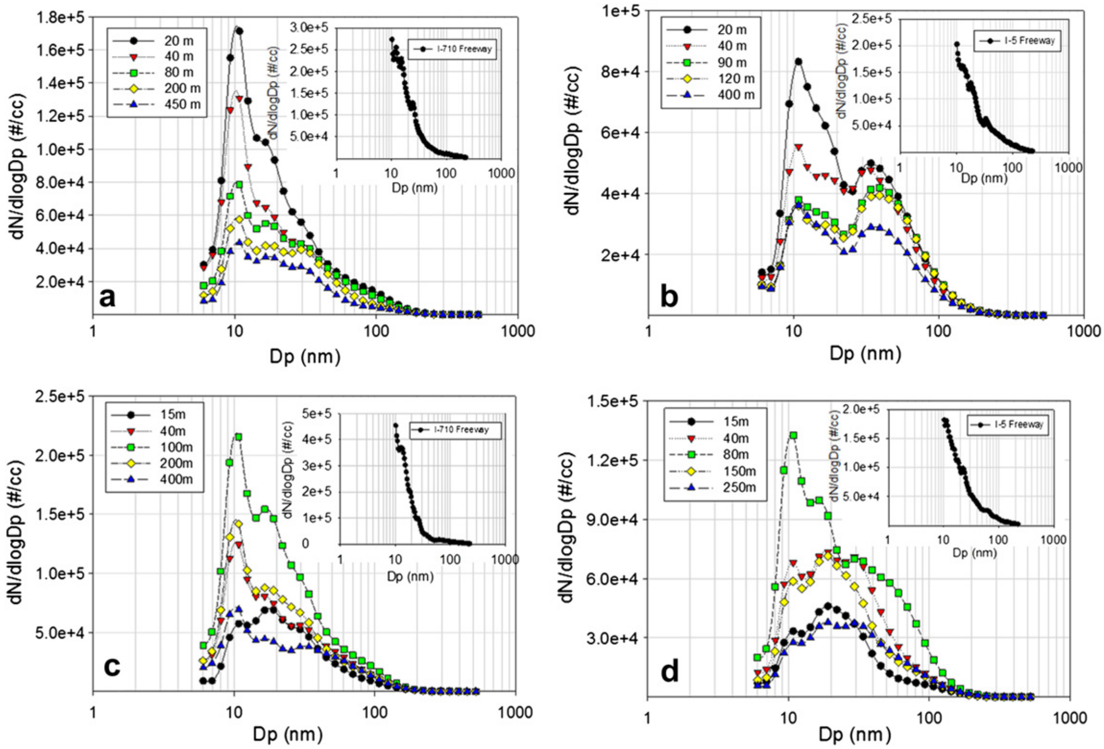

Fig. 2. Particle size distributions measured at various distances downwind of freeway using FMPS (6–523 nm) and in the immediate proximity of freeway using SMPS (10–225 nm) shown as subplot: (a) I-710 without roadside barrier; (b) I-5 without roadside barrier; (c) I-710 with roadside barrier; (d) I-5 with roadside barrier.

measured in the immediate proximity of the freeways using the SMPS (10–225 nm) are also included as subplots in the figures for comparison. For all plots, the horizontal axis represents particle size on a log scale while the vertical axis represents normalized particle number concentration. Data points represent averages from multiple scans taken at a given sampling location.

As shown in Fig. 2a and b (subplots), the particle size distributions in the immediate proximity of both freeways displayed a unimodal shape, with a distinct peak at approximately 10 nm (~10 nm), indicating new particle formation by nucleation of supersaturated semi-volatile organic vapors in the exhaust (Alam et al., 2003). Shortly after highly concentrated vapors (i.e. semi-volatile organic compounds) are emitted from the tailpipe of vehicles on freeway, the rapid cooling in the atmosphere causes them to nucleate and form large numbers of nucleation mode particles (Zhang and Wexler, 2004). The peak modal concentrations at ~10 nm are 2.7e5 and 2.0e5 particles cm^{-3} for I-710 and I-5 freeways, respectively.

As particles were transported away from the freeway, the particle size distributions changed markedly, with a dramatic decrease in the number concentrations. In Fig. 2a, the particle number concentrations at ~10 nm were 1.7e5, 1.3e5 and 7.9e4 particles cm^{-3}, at 20 m, 40 m, and 80 m, respectively, which accounted for only 63%, 48%, and 29% of that measured in the immediate proximity of freeway. Similar observations were also reported by Zhu et al. (2002b) near another freeway (I-405) in Southern California. Several atmospheric processes may contribute to this significant change in size distribution and concentration, including particle evaporation and diffusion (Hinds, 1999) and semi-volatile vapor condensation (Zhang et al., 2004). Due to their small size, particles of 10 nm have much higher diffusion coefficients than larger particles, and the dynamics of their evaporation are more pronounced due to the "Kelvin effect" (Hinds, 1999). The evaporated organic vapors, in addition to those from fresh vehicle emissions, may also condense onto pre-existing particles and form larger size particles. Although it was hypothesized the collision of small particles by coagulation may contribute to the deceasing particle number concentration (Zhu et al., 2002b), previous experimental measurement (Shi et al., 1999) and theoretical studies (Vignati et al., 1999; Zhang et al., 2004) have indicated that the role of coagulation is rather negligible in affecting the overall decay in particle concentration. At 200 m, the particle size distribution displays a broad shoulder between 20 and 50 nm, similar to that measured at 450 m, a clear indication that the particle concentrations have reached background levels at 200 m where the size distributions no longer change significantly with distance.

On the other hand, Fig. 2b shows the particle size distributions at various distances downwind of the I-5 freeway. In contrast to the observations near I-710, the particle size distributions displayed a consistent bimodal trend. The first mode appeared at ~10 nm, similar to the measurement near I-710 freeway, while there existed a distinct second mode in the larger size range of 30–50 nm. At 20 m, the modal concentration at ~10 nm was 8.3e4 particles cm^{-3}, nearly half of that measured in the immediate proximity of the freeway, indicating rapid dilution and the associated particle evaporation and diffusional loss. Compared with the corresponding downwind distance of I-710 freeway, the ~10 nm modal concentration is significantly lower at the I-5 site, whereas the second peak, observed at around 35 nm, has similar concentrations at sites near both freeways, resulting in a pronounced dip at ~25 nm in the bimodal distributions at the I-5 sites. The lower nucleation mode particle concentrations indicate a lower strength of fresh traffic emissions at the I-5 freeway, with much lower traffic flow than the I-710 (~8500 vehicles $hour^{-1}$ on I-5 versus ~12 200 vehicles $hour^{-1}$ on I-710). As the particles are further transported away from the freeway, particle number concentrations gradually decrease at both modes, and the second mode is shifted from 34 nm (at 20 m) to about 40 nm (at 120 m), indicating the possibility of small particle evaporation and vapor condensation onto pre-existing particles

(Shi et al., 1999; Zhang et al., 2004) as well as possible coagulation at different dilution conditions (Hinds, 1999; Zhu et al., 2002b). At 120 m, the nucleation mode particles at ~10 nm reached a concentration of 3.6e4 particles cm^{-3}, similar to the background level at 450 m; however, number concentration of particles at the larger size mode of 39 nm continued to drop after 120 m until it reached background levels at 400 m. Nucleation mode particles have a shorter residence time in the atmosphere, so they decay much faster and reach background levels at a shorter distance than larger particles (Raes et al., 2000).

Fig. 2c and d show the average particle size distributions at various distances downwind of the sections of I-710 (15, 40, 100, 200, 400 m) and I-5 (15, 40, 80, 150, 250 m) freeways with roadside noise barriers. Compared with the non-barrier sites, the particle size distributions and number concentrations were consistent at the same freeway when the traffic volume and fleet composition were relatively consistent during the days of sampling. As shown in both figures, with increasing downwind distance from the freeways, the evolution of particle size distributions displayed a dramatically different pattern with those at the non-barrier sites: the size distribution at distances close to the freeway (15 m) in the barrier sites showed significantly lower number concentrations for both freeways, while the peak size distribution and particle concentrations appeared at further downwind distances of 80–100 m, followed by a gradual decrease in concentrations until they reached background levels at beyond 250 m.

As shown in Fig. 2c, at 15 m downwind of I-710 freeway, particle size distributions displayed a uni-modal trend, with a slight peak at 10 nm and a broad shoulder at 16–19 nm. The 10 nm modal concentration is 5.7e4 particles cm^{-3}, i.e. significantly lower than that (1.7e5 particles cm^{-3}) measured at a similar downwind distance (20 m) without roadside noise barriers, as shown in Fig. 2a. A similar trend was also observed at 15 m downwind of I-5 with a roadside barrier (shown in Fig. 2d) where the peak modal number concentration at 10 nm was 3.1e4 particles cm^{-3}, 64% lower than that (8.5e4 particles cm^{-3}) measured at 20 m from non-noise barrier site. Modeling results have shown that the presence of a roadside noise barrier alters the dispersion patterns of traffic emissions and the trajectory of particles traveling downwind from their source (Bowker et al., 2007). The freeway vehicular emissions travel upward from the road level due to the presence of the roadside barrier, effectively inducing an "elevated" source. In the lee of the roadway noise barrier, vertical mixing occurs due to strong turbulence (Finn et al., 2010) creating a well-mixed downwind side zone with relatively lower pollutant concentrations. Depending on the road configuration and meteorological conditions, the recirculation cavity may extend from 3 to 20 times the noise barrier height (Baldauf et al., 2008b; Heist et al., 2009). The particle number concentration deficits observed in the downwind vicinity of the noise barrier strongly support the existence of a recirculation cavity as reported in literature (Bowker et al., 2007; Baldauf et al., 2008b; Finn et al., 2010).

With increasing downwind distance from freeways, particle number concentrations gradually increased and the nucleation mode at ~10 nm became more pronounced, indicating the diminishing of the recirculation cavity and the increasing influence of freeway emissions. At 40 m, the modal concentration at ~10 nm was 1.2e5 and 6.8e4 particles cm^{-3} for I-710 and I-5 freeway, respectively, about two times higher than those measured at 10–15 m. As the particles are further transported away from the recirculation cavity, the elevated source follows its trajectory and the plume gradually reattaches to the ground (Bowker et al., 2007). The peak size distribution and number concentration were observed at 100 m and 80 m for the I-710 and I-5 freeway, respectively. For the I-710, the modal concentration of 10 nm at 100 m is 2.2e5 particles cm^{-3}, 55% of that measured in the immediate proximity of freeway (4.0e5 particles cm^{-3}). The uni-modal particle size distribution at 100 m also resembles that observed at 20 m near non-barrier I-710 freeway (Fig. 2a). It displays a similar level of nucleation mode peak concentrations, thus indicating similar dilution -induced particle evaporation and a more pronounced shoulder at 19 nm, which may be attributed to re-condensation of the evaporated semi-volatile species, as argued by Zhang et al. (2004). This is also confirmed by similar observations at the I-5 freeway, where the particle size distribution at 80 m with roadside barriers (Fig. 2d) has a broader second mode at ~30 nm (7.0e4 particles cm^{-3}), in contrast to the corresponding peak at 20 m (5.0e4 particles cm^{-3}) near non-barrier I-5 (Fig. 2b). In comparison to similar downwind distance between the sites, the total number concentration at 100 m downwind of freeway with roadside barrier was 1.9 and 2.2 times of that at 80–90 m for non-barrier I-710 and I-5 freeway, respectively. Previous investigations have shown that particle number concentrations reach the background levels at a distance of 100–200 m downwind of freeway, depending on wind speed and meteorological conditions (Zhu et al., 2002b). The observations made in this study indicate that the presence of roadside noise barriers dramatically changes particles dispersion profiles and affects their concentrations distribution downwind of the freeway. At 200 m downwind of I-710 with roadside barriers, particle size distribution still displays a sharp uni-modal shape, with peak concentrations of 1.4e5 particles cm^{-3} at 10 nm, which is 2.5 times the background level measured at 200 m for the I-710 site without roadside barrier. A similar observation can also be made for the I-5 freeway at 150 m downwind of the barrier, where the ~10 nm modal concentration is 1.6 times that measured at corresponding distance of 120 m for the non-barrier I-5 sites.

As the particles traveled further downwind at 400 m near I-710, the particle size distribution and number concentration reached the background level as shown in Fig. 2c. The much longer downwind distance (400 m versus 200 m) needed to reach background levels indicates a larger impact zone from traffic emission sources for freeway sections featured with roadside noise barriers. For I-5 freeway with roadside barrier, the background level of particle size distribution and concentrations was reached at 250 m, as shown in Fig. 2d. The difference of the needed distances to reach background levels between the two freeways may be explained by the higher initial particle number concentration at the I-710, thus the longer time necessary for it to decrease to background concentrations.

3.3. Particle number and concentrations at different downwind distances

Fig. 3 shows the particle number (primary *Y* axis) and mass concentrations (secondary *Y* axis) with increasing downwind distances of the freeways without (Fig. 3a and b) and with (Fig. 3c and d) roadside noise barriers. The data points at $x = 0$ m represent the average number/mass concentrations in the immediate proximity of the freeways derived from SMPS (10–225 nm) while data points beyond $x = 0$ m represent average number/mass concentration downwind of the freeways as derived from FMPS measurement (6–523 nm). The corresponding error bars denote one standard deviation of measured particle number or mass concentration. Due to the different size ranges of the measurements, the data points derived from FMPS and SMPS were plotted separately in the figures for clarity.

As shown in Fig. 3a and b, total particle number concentrations measured in the immediate proximity of I-710 (1.2e5 particles cm^{-3}) were higher than I-5 freeway (8.0e4 particles cm^{-3}) due to the higher total traffic volume on the I-710. As the downwind distance increased, the number concentrations decayed exponentially due to the evaporation of semi-volatile particles and the diffusion of

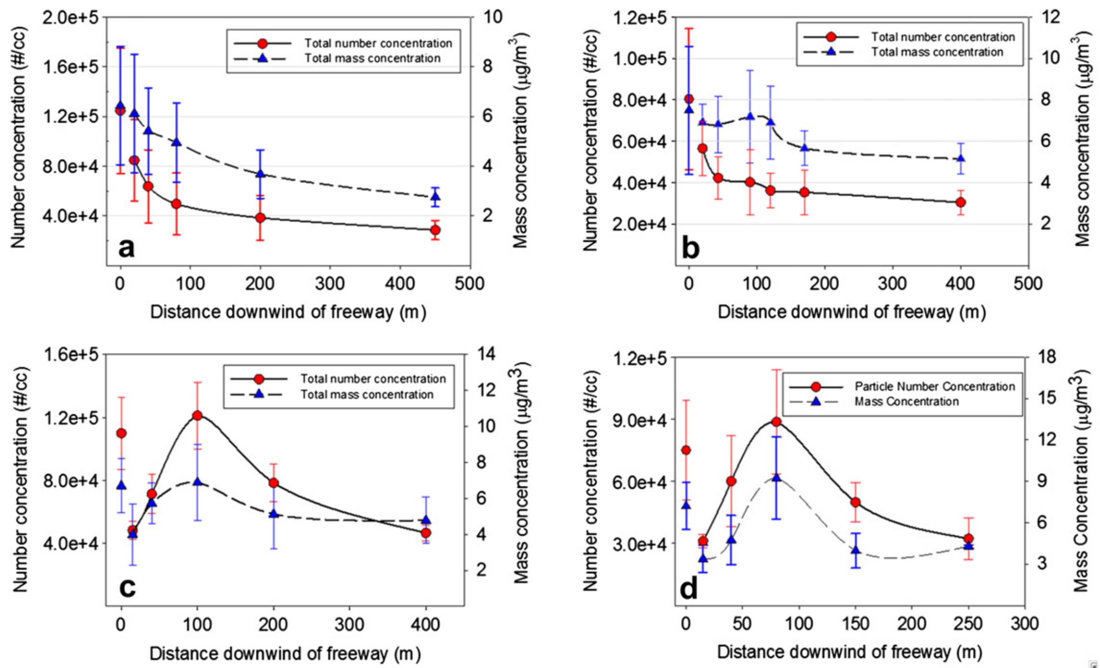

Fig. 3. Particle number and mass concentrations at different distance downwind of the freeway (a) I-710 no noise barrier (b) I-5 no noise barrier; (c) I-710 with noise barrier; (d) I-5 with noise barrier. Note: The total particle number and mass concentrations at $X = 0$ are derived from SMPS (10–225 nm) data at stationary sampling station; the concentrations at $X > 0$ are derived from FMPS (6–523 nm) data.

nucleation mode particles, as discussed in detail in the previous section. The concentrations reached background levels within 200 m and 120 m for I-710 and I-5, respectively, where the measured number concentration was only 45% and 64% of that measured at 20 m near its corresponding freeway. For both sites, the observed background particle number concentrations were similar at 3.0e4 particles cm^{-3}, which is a very typical urban background level across the Los Angeles Basin during that time period (Westerdahl et al., 2005; Moore et al., 2009). The faster decay trend for I-710 freeway may be attributed to the higher initial particle number concentration observed inside the I-710. Similar to the overall decay trend of number concentration, the total mass concentration (for the range of 6–523 nm) also decreased with increasing downwind distance in both freeways. However, the decay of mass concentration is much slower than number concentrations, as shown in Fig. 3a and b. The rapid dilution next to the freeway not only lowers particle concentration by dispersion, but also causes evaporation of semi-volatile species off the particle surface, which is more pronounced with decreasing particle size, due to the Kelvin effect (Hinds, 1999). The overall result is an accelerated decrease in number concentrations of smaller than larger particles. The evaporated vapors from the smaller range of ultrafine PM, combined with those from fresh vehicle emissions, may further condense onto pre-existing particles, resulting in a slower decay of particle mass concentration. At 200 m, the particle mass concentrations were 3.7 and 5.6 μg m^{-3} for I-710 and I-5, respectively, and are comparable to those measured at 400 m, suggesting that PM mass concentration also reached background levels within 200 m.

Fig. 3c and d show the particle number and mass concentrations in the immediate proximity and downwind of I-710 and I-5 with roadside noise barriers. Compared with those at non-barrier freeway sites, the particle concentration distribution displayed a significantly different trend, exemplifying the impact of a roadside barrier on the particle dispersion profiles. At 15 m, particle number concentrations were 4.8e4 and 3.1e4 particle cm^{-3} at I-710 and I-5 sites, respectively, 43% and 45% lower than those measured at 20 m downwind of corresponding freeway without roadside barrier. A similar trend was also observed for particle mass concentrations at the same sites. The particle concentration deficit observed at 15 m strongly underscores the existence of the recirculation cavity in the lee of the roadway barrier (Bowker et al., 2007; Baldauf et al., 2008b). As the downwind distance increased, the particle concentrations increased and reached a maximum at 100 m and 80 m for I-710 and I-5, respectively. The peak particle number concentrations are 2.4 and 2.2 times higher than those observed at corresponding distance for non-barrier sites at the I-710 and I-5 freeways. As the aerosols traveled further downwind, the particle number concentrations gradually decreased and reached background levels at 400 m; while the particle mass concentrations became stabilized to background levels earlier, at 200 m. The differential trend of particle mass and number concentrations highlights the role of semi-volatile species evaporation and re-condensation in the dynamics of particles evolution in the atmosphere (Vignati et al., 1999; Zhang et al., 2004; Ning and Sioutas, 2010). It is noted that a similar trend is also observed next to the freeways without roadside barriers (Fig. 3a and b), where particle mass concentration decayed much slower than number concentrations during the rapid dilution.

3.4. Size-segregated particle number concentrations at different downwind distances

Fig. 4 shows the average size-segregated particle number concentrations at different distances downwind of the freeways. The particle size distributions measured by FMPS (6–523 nm) were segregated into five different mobility size ranges of 6–25, 25–50, 50–100, 100–300 and 300–550 nm, respectively. The measured number concentrations in the size bins within each size range were added to derive the concentration of each size group.

As shown in Fig. 4a and b, particles in different size ranges behaved quite differently as the distance from freeways increased. The number concentration of particles in the size range of 6–25 nm

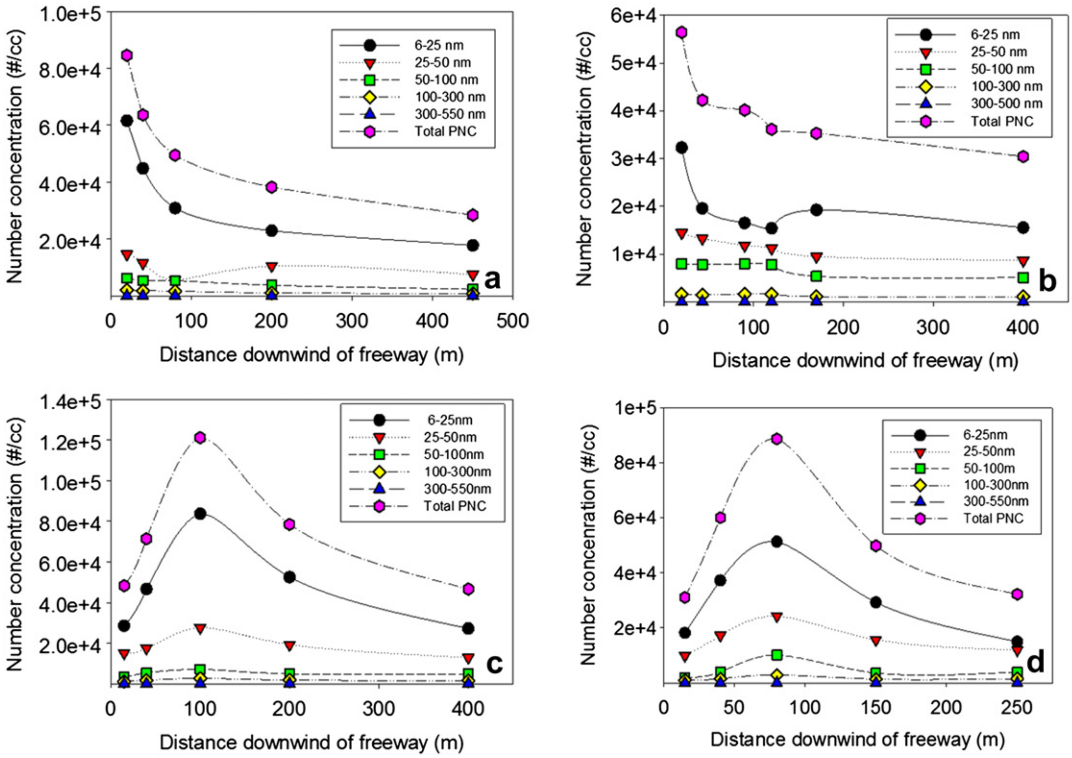

Fig. 4. Size-segregated particle number concentrations at different distances downwind of the freeway (a) I-710 no noise barrier (b) I-5 no noise barrier; (c) I-710 with noise barrier; (d) I-5 with noise barrier. Note: Total PNC is the total particle number concentration derived from FMPS.

accounted for 73% and 57% of the total number concentration at 15 m next to I-710 and I-5 freeways, respectively. The large fraction of <25 nm particles is consistent with the observation of Ntziachristos et al. (2007) and Zhu et al. (2002b) conducted next to the same freeway. As the particles are advected away from freeway, the 6–25 nm particles number concentrations decreased by half from 15 m to 80–90 m for I-710 and I-5, respectively, and gradually leveled off beyond 200 m. This observation is also reflected in the rapid drop of the nucleation peak displayed in the particle size distribution plots (Fig. 2a and b) from nearby the freeway to 100 m downwind. With increasing particle size, number concentrations decayed more slowly, illustrating the effect of size-dependent particle evaporation due to the Kelvin effect, and diffusion during rapid dilution. On the other hand, particles above 100 nm did not experience a substantial change in their number concentration with increasing downwind distance to the freeway, suggesting the insignificant contribution of freeway emissions to their concentrations in the atmosphere. Fig. 4c and d show size-segregated particle number concentrations for the barrier sites for I-710 and I-5 at various downwind distances. Close to the freeways at 15 m, the particle number concentrations in all size ranges were significantly lower than those at similar distances in non-barrier conditions and even comparable to those measured at background, a clear indication that the presence of roadside barrier induces a recirculation cavity in the lee of the barrier with deficit of pollutants concentrations. An evident peak of particle number concentrations in the ranges of 6–25 nm, 25–50 nm and 50–100 nm is observed at 100 m and 80 m for I-710 and I-5, where the reattachment of pollutants plume from traffic emissions occurs. Compared to the non-barrier freeway conditions, the number concentrations of particles in different size ranges near barrier freeway reached background levels at a farther distance of 400 m and 250 m for I-710 and I-5 freeways.

3.5. Co-pollutants concentrations at different downwind distances

Fig. 5 shows the concentrations ratios of carbon monoxide (CO), nitrogen dioxide (NO2) and black carbon (BC) at various distances downwind of the freeways with no roadside noise barrier (3a: I-710; 3b: I-5) and with barrier (3c: I-710; 3d: I-5). The concentration ratios were calculated by dividing the average concentrations measured at different downwind distances by the average concentrations in the immediate proximity of the freeways ($x = 0$). Error bars represent one standard deviation of the average ratios. CO concentrations for I-5 were expressed as absolute downwind concentrations in the secondary *Y* axis due to a malfunction of the CO monitor used at the site in the immediate proximity of I-5. These species were selected because their concentrations in urban environments are closely related to traffic emissions. For the concentration ratios in Fig. 5a and b, exponential decay curves were used to fit the decreasing ratios with increasing downwind distances. The best fitting decay equations and their corresponding R^2 values are listed in Table 3.

As shown in Fig. 5a and b, all pollutants concentration ratios decreased exponentially with increasing downwind distances of the freeway. For the gaseous species of CO and NO_2, their concentrations decreased by 70–80% within the first 100 m for both freeways. Particle-bound BC concentration dropped by 60% and 80% in the first 100 m for I-710 and I-5, respectively. Within 150 m, all pollutants concentrations reach asymptotically background levels. Similar observations have been reported extensively in the recent literature (Zhu et al., 2002b; Baldauf et al., 2008a; Clements et al., 2009). As shown in Table 2, the decay coefficients of NO_2 and BC for I-710 were consistently higher than that for I-5, suggesting a faster decay of their concentrations near the I-710 freeway. This may be explained by their higher initial concentrations of these pollutants at the I-710 freeway, which has a roughly 50% higher

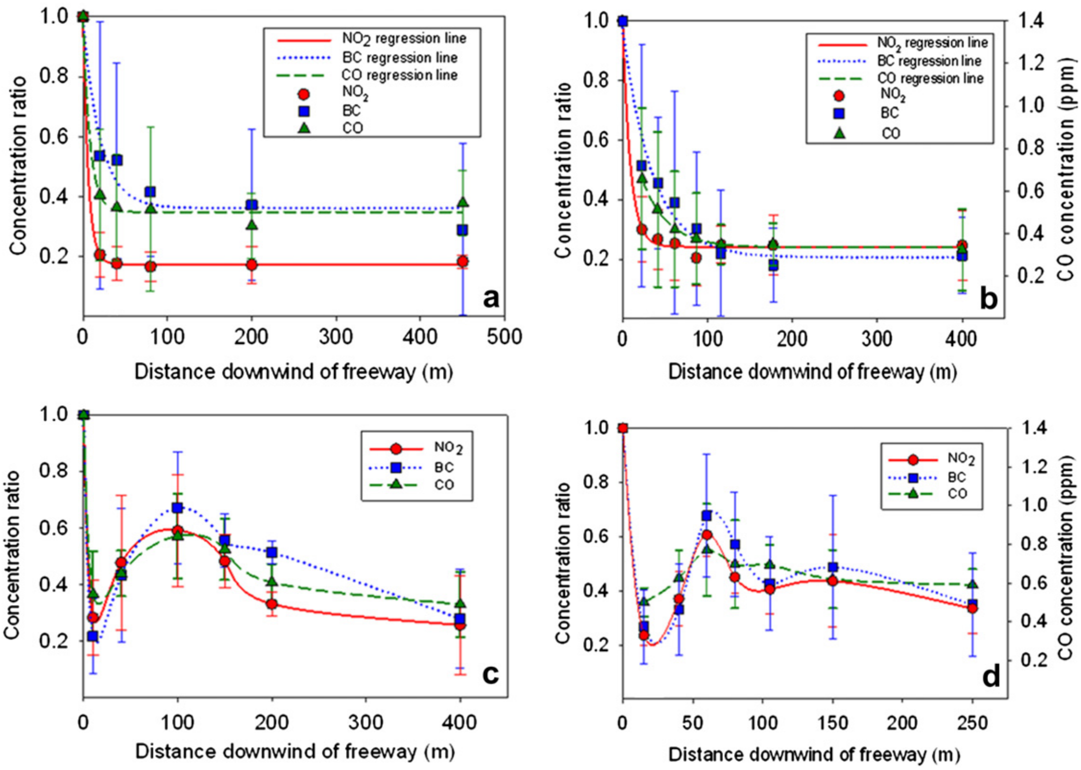

Fig. 5. BC and gaseous pollutants normalized concentrations at different distance downwind of the freeway (a) I-710 no noise barrier (b) I-5 no noise barrier; (c) I-710 with noise barrier; (d) I-5 with noise barrier.

traffic volume than the I-5 freeway. Other meteorological conditions and the local topography may also contribute to the decay curves of air pollutants from the freeway (Zhu et al., 2004), but given the overall similarity in both of these sets of parameters between the two freeways, we attribute the faster decrease in the I-710 to the higher traffic volume in that freeway.

In contrast, the concentration ratios downwind of the freeway sections with roadside noise barriers displayed a different trend, as shown in Fig. 5c and d. At downwind distance of 15 m, the closest location downwind of the I-710, the pollutants concentration ratios were 0.36, 0.28 and 0.22 for CO, NO_2 and BC, respectively, comparable to the background levels measured at 400 m (0.33, 0.26, and 0.28 for CO, NO_2 and BC, respectively). The low concentration ratios are consistent with the observations of particle number and mass concentrations, due to the strong turbulence that exists in the recirculation cavity of the roadside noise barrier (Finn et al., 2010). At 80–100 m, where the concentrations have dropped to background levels for the non-barrier sites (Fig. 5a), the pollutants displayed a peak ratio of 0.57, 0.59, and 0.67 for CO, NO_2, and BC, respectively, as shown in Fig. 5c for the I-710 with barrier. The dramatic difference of the pollutant concentration profiles downwind of the freeway underscores the impact of roadside noise barrier on pollutant dispersion. As the pollutants are transported further away from freeways, their concentrations gradually decrease and reach background concentrations at 400 m and 250 m for I-710 and I-5, respectively. The results suggest that the freeway roadside features, such as noise barriers, should also be taken into consideration in assessing public exposure to ambient pollutants from traffic emissions in the community nearby busy freeways.

Table 3
Concentration decay curve equation and coefficients ("*x*" is the distance downwind of the freeway from the stationary sampling station; "*y*" is the normalized concentration ratio).

	NO_2	BC	CO
I-710	$y = 0.17 + 0.83$ $e^{(-0.16x)} R^2 = 0.99$	$y = 0.36 + 0.63$ $e^{(-0.05x)}\ R^2 = 0.97$	$y = 0.35 + 0.65$ $e^{(-0.12x)}\ R^2 = 0.99$
I-5	$y = 0.24 + 0.76$ $e^{(-0.11x);}\ R^2 = 0.99$	$y = 0.21 + 0.77$ $e^{(-0.03x)}\ R^2 = 0.98$	–

4. Summary and conclusions

The present study investigated the evolution of particle size distributions and pollutants concentrations downwind of two major freeways (I-710 and I-5) sections in Southern California, both featured with and without roadside noise barriers. The results corroborate those of earlier studies by showing that the particle number and pollutants concentrations decay exponentially near freeways without the roadside noise barriers. Particle number concentrations decrease sharply with distance from the freeway, especially for smaller (<30 nm) particles due to evaporation and diffusion. The background pollutant concentrations are reached within 150 m downwind of freeway without roadside barriers.

With the presence of roadside barrier, the dynamics of particle and co-pollutants dispersion change dramatically. A recirculation cavity is formed in the close vicinity downwind of the barrier, as observed at 15 m in the present study, resulting in a concentration deficit zone in the lee of the barrier, where the particle number concentrations are 45–50% of those measured at similar downwind distances of freeways without roadside barrier. The particle size distributions and co-pollutants concentrations were comparable to background levels. With the increasing downwind distance, particles and gaseous co-pollutant concentrations increase and peak at 80–100 m, where the plume of elevated traffic emissions sources reattaches to the ground. The particle size distribution displayed a sharp nucleation mode peak, with total number concentrations

1.9–2.2 times of those at similar distance near non-barrier freeways. Particle mass, CO, NO_2 and BC also reached maximum concentrations ratios. The background particle and co-pollutants concentrations were reached at distances of 250–450 m, farther than the sites near non-barrier freeways.

The much longer downwind distance needed to reach background levels indicates a larger impact zone of traffic emission sources near the freeways with roadside noise barriers. Our results suggest that freeway roadside features, such as noise barriers and plantation, should also be taken into consideration in assessing population exposure to ambient particles and co-pollutants from traffic emissions.

Acknowledgements

We would like to acknowledge Dr. Katharine Moore for her significant contributions in the implementation of experiment. Also, we would like to thank Ali Attar, Kalam Cheung, for their assistance in the field and data work, and the support of University of Southern California Provost's Ph.D. fellowship. This study was funded by EPA under the STAR program through grant RD-8324-1301-0 and by California Air Resources Board through ARB Contact 05-317 to the University of Southern California.

MEMORANDUM

To: Mark Stehly

From: Rob Scofield and Linda Hall

Subject: **Draft Environmental Assessment for the BNSF Intermodal Facility Proposed by BNSF Railway Company near Gardner, in Johnson County, Kansas**

This memorandum addresses two broad issues either raised in or implicit to the comments on the **Draft Environmental Assessment for the BNSF Intermodal Facility Proposed by BNSF Railway Company near Gardner, in Johnson County, Kansas** (EA) submitted by Andrea Hricko (University of Southern California) and by the Natural Resources Defense Council (NRDC) specifically:

1. The reasons that health risks calculated for railyards in California are not directly applicable to the Gardner, Kansas facility; and
2. The reasons USEPA cited for their conclusion that the approach adopted by California for quantifying cancer risk is not valid.

In the following discussion, we address each of these issues in turn.

1. **The reasons that health risks calculated for railyards in California are not directly applicable to the Gardner, Kansas facility;**

   Expanding on the comments by Harold Holmes of California's Air Resources Board (CARB) (Kansas City Star, 2007) on this topic, we note that the physical features of any air emission source have an important influence on the estimated air concentrations and health risks. In particular, the proximity of houses to specific rail yard operations will have substantial influence on the risks estimated for the Maximally Exposed Individual (MEI); and when discussing estimated risks for rail yards the estimated risk at the MEI is the value most commonly cited. Estimated risks are also dependent on specific assumptions for emissions, dispersion, exposure and toxicity of chemicals. For any particular evaluation, the selection of these assumptions is guided by local regulatory authorities. California has specific assumptions that must be used for emission factors, dispersion modeling, exposure frequency, and toxicity of chemicals (e.g. diesel exhaust). Some of the assumptions required for use in California differ substantially from the USEPA guidelines used for the Gardner evaluation. Accordingly, estimated health risks for identical facilities in California and Kansas would be quite different because of the distinct set of guidelines used in each analysis. Simple ratios between the number of lifts and estimated health risks, such as are discussed in comments on the EA, are not valid.

   Among the more important specific factors rendering invalid the use of ratios between measures of throughput (e.g., numbers of lifts) and estimated health risks are the fact that each railyard is distinct with respect to the local meteorological conditions, the type of equipment used, the activity patterns of the equipment, and the location and number of people who work or live in the vicinity or each yard Additionally, California calculates cancer risk from DPM based on an approach that has been rejected by the USEPA. These differences are discussed below.

Meteorology. The local meteorologic conditions in the vicinity of a railyard, such as predominant wind speed and direction, temperature, barometric pressure, and cloud cover (as well as the variability in each of these factors), are key determinants of any potential health effects associated with the yard. These factors are important in that the local meteorology governs the direction that emissions might be carried and the extent of their dispersal. Because of the significance of these parameters to health effects estimation, the USEPA has strict meteorologic data requirements for modeling emissions. These requirements are for one-year or five years of representative data on each of the aforementioned parameters, depending on whether the data were obtained on-site or off-site, respectively (USEPA, 2005). Meteorological data cannot be extrapolated between railyards (or between any other facility) unless they are in direct proximity to each other. Consequently, it is clear that extrapolation of such data between California and Kansas - states with dramatically different climate and meteorological regimens - is not supported (USEPA, 2004a,b; 2005). The statement that,"[s]ince the wind at the Gardner IMF proposed location apparently blows toward the town of Gardner, including toward a subdivision and two schools within a mile of the proposed IMF, there is every reason to believe that there will be elevated cancer risks as a result of the Gardner IMG (sic)", has no technical merit, cannot be substantiated, and is contradicted by the emission estimation, dispersion modeling, and health evaluation that was completed and included in the EA.

Equipment Usage and Activity. Commensurate with their individual design and geographic location, each BNSF railyard is used to conduct either different activities or a different combination of activities, and each uses a unique mix of equipment as a consequence. These differences have a substantial impact on the emissions from a railyard, making direct comparisons between yards invalid. For example, compared to BNSF's San Bernardino facility, the Argentine intermodal facility has approximately one-third fewer lifts, and compared with BNSF's Hobart yard about 70% fewer lifts. The Argentine intermodal facility has less classification and train building activity compared to other intermodal facilities, so the switching engines have fewer hours of activity relative to the number of lifts. Additionally, the majority of the arriving and departing trains at the Argentine facility are of the "setout" type, which only stop to cut off rail cars before moving on. This reduces the line-haul locomotive activity, especially idling, compared to San Bernardino or Hobart. Also, there are very few refrigerated containers with auxiliary diesel engines operating at Argentine. Lastly, while Argentine activity levels have been used to project future lift levels at the proposed new intermodal facility, the new facility will have several design features that will minimize emissions compared to even Argentine. These include electric overhead cranes, automated gate technology for truck arrivals and departures, and long tracks to accommodate whole trains, thus minimizing switch locomotive usage.

Impacted Communities. Any calculated impacts from a railyard are also a function of the proximity and number of individuals in the vicinity – factors that are unique to each railyard, and which preclude direct comparisons of health effects between yards. For example, Harold Holmes of the CARB has noted (Kansas City Star, 2007) that the CARB estimated relatively high cancer risks from the BNSF San Bernardino yard because individuals lived in the immediate vicinity of concentrated emissions. However, higher emissions at the BNSF Barstow yard did not have comparable risks because emissions were dispersed prior to reaching the local community.

Furthermore, many of the health studies cited by Ms. Hricko and the NRDC as evidence of railyard-related health impacts are studies of populations exposed to multiple sources of industrial and transportation-related emissions (e.g., freeways) and photochemical smog in southern California, and the implication that the health effects observed in these studies can be attributed to emissions from one or more intermodal railyards in southern California is misleading. To further imply that such health effects could be expected from a single intermodal railyard in Kansas, or anywhere else, is even more misleading.

To address the noncancer health effects of diesel exhaust, the USEPA has developed a Reference Concentration. As shown in the EA, the exposure to diesel exhaust from the Gardner facility would be less than the USEPA exposure limit designed to prevent noncancer health effects (i.e. the Reference Concentration).

<u>Calculation of Cancer Risks</u>. For reasons explained in more detail below, the approach required in California for estimating cancer risks from diesel emissions was explicitly rejected by the USEPA as a valid way to evaluate cancer risks from diesel emissions. Because California's approach to estimating cancer risk is not accepted outside of California, any comparison of cancer risks from California rail yards to the Gardner facility is not applicable.

2. **The reasons USEPA cited for their conclusion that the approach adopted by California for quantifying cancer risk is not valid.**

Diesel exhaust is a complex mixture of hydrocarbons, particulates, gases, water, and other compounds (the precise composition of the mixture depends on many factors, including the fuel source, engine type, engine age, and operating condition). For both the USEPA and California, the general approach to estimating cancer risk from exposure to mixtures - such as combustion exhaust - is to select a subset of so-called indicator chemicals (e.g., the principal components of the exhaust), multiply the estimated concentration of each by a chemical-specific cancer slope factor (CSF), and then add the risks estimated for each indicator chemical. That is, the sum of the health risks from each individual chemical is used as an estimate of the risk posed by the mixture as a whole. Under current USEPA risk assessment practice this approach is used, for example, when estimating health risks from combustion of fuels such as gasoline, fuel oil, wood, natural gas, etc. While California also generally relies on this indicator chemical approach for quantifying cancer risks from mixtures, they have developed an alternative approach for quantifying cancer risks from diesel exhaust. In contrast to the approach used for other mixtures, California developed a CSF to represent the carcinogenicity of the entire mixture of chemicals in diesel exhaust, using diesel particulate matter (DPM) as a surrogate for that mixture (Office of Environmental Health Hazard Assessment [OEHHA], 1998). Both California and the USEPA have adopted a concentration limit of 5 ug/m^3 for diesel exhaust particulate matter (DPM) as a way to evaluate the noncarcinogenic health effects of diesel exhaust.

California's CSF was developed from epidemiology studies on rail road workers in which quantitative correlations were drawn between exposure to diesel exhaust and the incidence of lung cancer. Whether these epidemiology studies are adequate to support development of a CSF for diesel exhaust, using DPM as a surrogate, is the central issue in the different approaches used to quantify diesel exhaust-attributable risk by California and the USEPA.

One of the studies central to California's analysis was that of Garshick et al. (1988). The Garshick et al. (1988) study represents a retrospective analysis of 55,407 white male railroad workers from across the U.S. The lung tumor incidence for these railroad workers was reported in Garshick *et al.* (1987, 1988) and the estimated exposures were reported in Woskie *et al.* (1988a,b).

The USEPA (2002) identified a number of limitations in the Garshick et al. (1988) data, including:

- inadequate information on exposure to diesel exhaust (i.e., assigning who was exposed and who was not exposed),
- lack of knowledge of when workers first began working with diesel equipment, and
- lack of information on smoking and other lifestyle correlates of lung cancer risk.

Of particular concern to the USEPA, to Dr. K. Crump (1991, 1999, 2001) and to the members of an expert panel[1] was the fact that lung cancer risks among the exposed workers decreased with increasing length of exposure – the opposite biological effect from what is expected for a carcinogen. Additionally, one of the categories of workers potentially exposed to high levels of DPM (shop workers), had no elevated cancer risk. Because of these findings, the USEPA has not adopted a CSF (or unit risk factor) for diesel exhaust emissions, stating that, "the available data are too uncertain at this time" (USEPA 2002).

We note that Garshick subsequently published the results of a longer follow-up study of the same workers and found the same trend (Garshick et al., 2004) - suggesting that the original observation of a negative correlation between exposure and lung cancer risk was not an artifact attributable to a truncated follow-up period. Despite the passage of seven years since the original analysis, the USEPA has not revised its position on the adequacy of available data on DPM, has not developed a CSF (USEPA, 2009), and has not adopted California's CSF for DPM.

While the USEPA approach to estimating health risks for mixtures is as discussed above, the USEPA and several states have elected to address the carcinogenicity of diesel exhaust by promoting emission reducing technologies without quantifying cancer risks.

RE: BNSF Intermodal Facility, Gardner, KS

Dear Mr. Stehly:

At the request of BNSF Railway Company, the Center for Toxicology and Environmental Health, L.L.C. (CTEH) is pleased to have the opportunity to review and comment on many of the toxicological issues that have been raised regarding potential health risks of the proposed intermodal facility near Gardner, KS. In particular, our review addressed comments provided by Andrea M. Hricko (Community Outreach and Education Program (COEP) of the Southern California Environmental Health Sciences Center) and Melissa Lin Perrella and Andrew E. Wetzler (National Resources Defense Council (NRDC)). Our comments are summarized below.

Acute health effects of diesel exhaust

Concerns have been expressed regarding the potential health effects of increased exposure to diesel exhaust as a result of increased traffic at the facility. At sufficient concentrations, exposure to diesel exhaust in air may be associated with various acute symptoms such as irritation of the eyes, nose, throat, and lungs, headache, lightheadedness, cough, and nausea (USEPA, 2002). In general these symptoms are transient and resolve quickly once an individual is removed from the exposure. Excessive exposures to diesel exhaust also have the potential to aggravate pre-existing respiratory problems such as asthma or chronic obstructive pulmonary disease (COPD). As with any chemical exposure, the key factor as to whether acute health effects will occur is based on the magnitude of exposure including the concentration in air and the duration of exposure. In terms of community exposures, predominant wind direction and distance from the source are key considerations in determining potential exposure levels as well.

In reviewing comments by the COEP and NRDC, we note that there is little or no discussion of the potential exposure levels to diesel exhaust that may result from the proposed facility. However, repeated references are made to studies which were performed by the California Air Resources Board (CARB) in their past evaluations of California railyards. For example, Ms. Hricko noted that the highest cancer health risks [and thereby the highest exposure levels] were found at the San Bernardino intermodal facility. In the risk assessment for this facility, it was noted that the hazard indices for non-cancer chronic risk health hazards were 0.05-0.3 (CalEPA, 2008). CARB noted that health hazard indices which are less than 1.0 are unlikely to be associated with potential non-cancer chronic public health risks. In this situation, CARB suggested that it was more reasonable to examine potential cancer risks rather than acute or chronic non-cancer risks.

CARB used a reference concentration of 5 μg/m^3 for inhalation exposure and noted that adverse health effects are not expected with exposures at or below this level. Furthermore, CARB notes that "it should be emphasized that exceeding the chronic reference exposure level does not necessarily indicate that an adverse health impact will occur." The hazard index is calculated by dividing the air concentration by the reference concentration. Calculated diesel PM levels for the San Bernadino risk assessment were thus 0.25-1.5 μg/m^3. Curiously, the estimated average statewide exposure to diesel PM_{10} for California in 2000 was 1.8 μg/m^3 (CalEPA, 1998)

The USEPA also used 5 μg/m^3 as a reference concentration for diesel PM exposure (IRIS, 2009). USEPA defines the reference concentration as "an estimate (with an uncertainty spanning perhaps an order of magnitude) of a daily inhalation exposure of the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime." In other words, the estimated diesel PM concentrations associated with the San Bernadino railyard were well below levels that are considered safe for a lifetime of exposure. In short, it is not reasonable to conclude that diesel PM would be associated with health effects in residents located near the railyard or by inference, a similar facility. These findings are not consistent with the NRDC suggestion that exposure to diesel PM in these circumstances will result in an increase in non-cancer health effects.

Carcinogenicity of diesel exhaust

Many of the comments regarding the proposed facility focused on potential cancer risks due to increased diesel exhaust exposures. In particular, Ms. Hricko noted that: "The EA fails to describe elevated cancer risks at other railyards including at numerous BNSF railyards in California" and that the highest risks were found at the intermodal facility in San Bernadino. Also, the California railyard risk assessments showed elevated levels of cancer risk extending more than one mile. The NRDC notes that while it is difficult to predict cancer risk, "data obtained from California railyards suggests, at the very least, that railyards of similar size and operations (and smaller) to the Proposed Project have been known to create significant health impacts." Extrapolation of the CARB risk assessment studies to the intermodal facility are problematic for a number of reasons and should not be directly applied.

First, the carcinogenicity of diesel exhaust has not been definitively established. Although the state of California considers diesel exhaust to be a known carcinogen, other public health agencies do not concur with such a strong conclusion. For example, the USEPA (2009) has noted that diesel exhaust is likely to be carcinogenic but identifies a number of limitations in determining the overall strength of the association. They note that while some animal studies have shown lung tumors with diesel exhaust exposure, effects have occurred in species which are more susceptible to tumors and occurred at relatively high exposure levels (i.e., >3500 μg/m^3) which are "far beyond the range of environmental levels." USEPA concludes that "The rat tumor occurrences, thus, are not particularly influential in judging the hazards at environmental levels of exposure." While a number of studies examining the association between *occupational* exposure to diesel exhaust and lung cancer have reported a small increased risk (i.e., relative risk typically less than 2.0), the studies are difficult to interpret due to poor exposure assessment and inability to eliminate potential confounding effects of smoking. Relative risk refers to the ratio of illness in the exposed population compared to an unexposed population. In contrast to California, the USEPA (2002) concluded that the diesel exhaust human exposure-response data are considered too uncertain to derive a confident quantitative estimate of cancer unit risk.

Assuming that diesel exhaust can cause lung cancer, it should be noted that studies which reported an association examined individuals with increased occupational exposures. Such exposures are not likely for individuals located at a remote distance from the source. Even under occupational exposure conditions, the relative risks in nearly all studies were significantly less than 2.0. The significance of relative risks less than 2.0 are regarded by epidemiologists as difficult to interpret due to the inability to reliably eliminate confounders. In the case of diesel exhaust and lung cancer, the biggest confounder is cigarette smoking. Occupational groups such as railroad workers and truck drivers which have been studied regarding diesel exhaust exposure and lung cancer are known to have high rates of smoking.

Second, risk assessments such as those performed by the CARB are not intended to prove that living near a railyard actually results in increased lung cancer rates. Furthermore, risk assessments of this type do not establish that railyards "have been known to create significant health impacts." In the CARB risk assessments, diesel exhaust exposure levels for residents living near the railyards were not measured and only estimated based on source emission estimates. A controversial cancer slope factor derived by the state of California was then applied to the exposure estimates to derive the potential number of cancer cases. Extremely conservative exposure assumptions were used such as exposure for 70 years, 24 hours a day, 7 days a week. Finally, there have been no published studies to determine whether residents living near the railyards actually have an increased rate of lung cancer. In short, the risk assessment information cannot be used to "prove" that living near a railyard or that diesel exhaust exposure actually causes increases rates of lung cancer.

Garshick studies

Much of the impetus for California's designation of diesel exhaust as a carcinogen are based on studies conducted by Garshick et al. beginning in the late 1980's. Garshick et al. (2004) was also cited by Ms. Hricko as evidence of the carcinogenicity of diesel exhaust. Due to the heavy reliance on the Garshick railroad study and its conclusions regarding diesel exhaust and cancer, it is reviewed below.

Garshick et al. (1988, 2004) examined lung cancer rates in a cohort of railroad employees who were age 40-64 in 1959 and had been employed for at least 10 years. Lung cancer rates in workers such as conductors and engineers, who were considered to have the highest exposure, were increased with a relative risk generally <1.5. In terms of relative risks, this is not a particularly strong association. For comparison, studies of lung cancer and smoking typically show relative risks for lung cancer 10 or more times higher than this. Younger workers tended to have a higher risk of lung cancer which was attributed to increasing use of diesel locomotives starting in the 1950's. Primary weaknesses of the study included a lack of exposure assessment for the employees, the absence of a clear dose-response relationship, and no information on smoking for the identified lung cancer cases. Although the studies claim to have controlled for smoking, smoking data was actually obtained from a different cohort of workers in which the next-of-kin were asked about smoking histories. This information was then applied to the study cohort and introduces significant sources of error and misclassification.

The lack of accurate information on known smoking rates in the study group is a glaring weakness. Railroad employees from the study timeframe were known to have extremely high smoking prevalence rates. Sterling and Weinkam (1976) reported in a 1970 survey that railroad conductors and engineers were among the 40 occupational categories with the highest percentage of smokers. A previous study by Garshick et al. (1987) of railroad retirees with more than 10 years of experience showed that 96% of the lung cancer cases were smokers and over 80% of the railroad worker controls were also smokers. In addition, over 90% of the cases and controls in which smoking information was available had smoked more than 20 years. Thus, smoking and even passive cigarette smoke exposure to individuals working alongside smokers is a significant confounder, particularly given the finding that lung cancer relative risks associated with exposure to passive cigarette smoke is similar to that reported in the Garshick studies for diesel exhaust exposure. In that time period, workers could smoke while on duty. Many of the other epidemiological studies which are often cited in support of an association between diesel exhaust and lung cancer, such as studies of truckers, suffer from the same limitations of limited exposure assessment and minimal, if any, information on smoking.

Smoking is estimated to account for 90% or more of all cases of lung cancer. Because it is such a strong confounder, Covey and Winder (1981) have noted that "an appropriate evaluation of an occupationally related disease also affected by smoking must include detailed and comprehensive smoking data." Speizer (1986) noted that "Because of the overwhelming effect of cigarette smoking, population-based studies that report on environmental effects, particularly at relatively low levels of excess risk (RR greater than 1.0 but less than 2.0), and that do not attempt to take cigarette smoking into account, must be considered seriously flawed. These studies, therefore, can contribute very little to our understanding of risk factors for respiratory cancer."

Additional perspective on the problem of smoking as a confounder in studies finding weak associations was provided by Sir Richard Doll, a renowned epidemiologist who stated that: "Lung cancer, of course presents a peculiarly difficult problem, because of its close dependence on cigarette smoking and the way smoking habits vary with geographical region and socioeconomic status...Unfortunately it is seldom, if ever, possible to assess the quantitative contribution of this factor to differences in the risk of lung cancer in different occupations, as we neither know the relative importance of smoking habits at different ages nor, if we did, do we usually have smoking histories available in sufficient detail to enable them to be taken into account. Nor is it likely that such detailed histories could now be obtained with sufficient reliability to enable them to be used, once an alternative explanation is known to be suspected" (Doll, 1985).

One of the factors that appears to be overlooked in the Garshick studies has been the association of increasing lung cancer rates which corresponded with increasing cigarette consumption in the U.S. after World War II. The Garshick cohort has been noted to show lower lung cancer rates in older workers who were employed in 1959 compared to their younger coworkers. The higher lung cancer rates in the younger workers were attributed to increased dieselization of the locomotive fleet around this time frame and increased opportunity for exposure to diesel exhaust while operating the diesel locomotives. However, 1959 also corresponds almost exactly to the peak prevalence of smoking in the U.S. (See Figure 1). The marked rise in lung cancer rates after 1950 closely parallels the increased cigarette consumption rates during that era (Figure 2). Thus, given that the actual smoking rates in the study participants were unknown, increased rates of lung cancer in younger workers from the cohort may be due to increased rates of smoking rather than a diesel exposure effect.

Hesterberg et al. (2006) noted similar weaknesses in their review of the literature on diesel exhaust exposure and cancer. They also note that studies of underground miners, who experience the highest occupational diesel PM exposures, generally do not show elevations in lung cancer. They concluded that "After decades of research involving numerous epidemiologic studies and extensive investigations in laboratory animals, a causal relationship between diesel exhaust exposure and lung cancer has not been conclusively demonstrated." Their conclusions were essentially the same as Muscat and Wynder (1995) who also reviewed the association between diesel exhaust and cancer and concluded: "Using common criteria for determining causal associations, the epidemiologic evidence is insufficient to establish diesel engine exhaust as a human lung carcinogen."

In summary, although California has chosen to regulate diesel exhaust as a known carcinogen, the evidence is far from convincing and is based largely on studies, including those by Garshick et al. with significant limitations.

Misleading statements regarding "cancer"

Reviewed comments have repeatedly suggested a link between diesel exhaust exposure and cancer. It should be noted that there are over 100 different types of cancer and the risk factors for each type of cancer are different. It is inappropriate to suggest that exposure to diesel exhaust will increase the rates of cancer in general in an exposed population. As discussed above, studies have primarily examined the association between diesel exhaust and lung cancer. Lung cancer is the most common cancer in U.S. adults. The overwhelming strongest risk factor for lung cancer is cigarette smoking which accounts for 90% of more of all cases. Relative risks of lung cancer due to smoking show an extremely strong and consistent relationship which has not been shown with studies of diesel exhaust. Diesel exhaust exposure is not a known cause of other types of cancer. There are no known studies which have shown an increase in lung cancer rates or cancer in general from diesel exhaust exposure among non-occupationally exposed individuals. It is misleading to insinuate that exposure to increased levels of diesel exhaust from the proposed facility will result in an increase of various other types of cancer.

Other non-cancer health effects

NRDC has suggested that railyards of comparable or even smaller size to the proposed facility have been known to create significant public health impacts. However, the specific health impacts at issue are not specifically defined by NRDC. As noted above, the California risk assessment studies were theoretical evaluations which did not identify a "known" health impact in surrounding communities. In addition, the risk assessments noted that the diesel exhaust exposure levels were significantly less than the reference concentration for non-cancer health effects and would not be expected to result in any adverse health effects, even with the conservative assumption of a lifetime of exposure, 24 hours a day, 7 days a week. Although comments have provided a number of inferences to increased levels of PM from the facility and their potential association with various health effects, the data cited in the California risk assessment does not necessarily support this observation or that PM levels in the community will be increased to levels of concern. It should be remembered that PM can be derived from many sources including automobile exhaust, wood burning, agricultural activities, and others. Epidemiological studies regarding PM and health effects may include PM from multiple sources other than diesel exhaust.

Review of cited studies regarding non-cancer effects

Ms. Hricko has provided a number of references to support her comments regarding the association between air contaminants and various health outcomes such as asthma, cardiovascular disease, diabetes, and low birth weight. Review of these studies indicates they have limited applicability in assessing the Kansas facility. For example, multiple studies were cited in which health effects were examined among children and/or adults living in several Southern California communities in close proximity to Los Angeles (i.e., Gaudereman et al., 2004; Gauderman et al., 2005; Gilliland et al., 2001; Kunzli et al., 2005; McConnell et al., 2006; Salam et al., 2005; Wilhelm and Ritz, 2005). However, no data was provided to indicate that exposures at the proposed facility are comparable in magnitude to that which occurs in the Southern California area secondary to the high of density freeways, vehicular traffic, and the meteorological and topographical conditions unique to that region that result in the familiar smog layer.

Several of the cited studies noted airborne pollutant levels decrease markedly within 150-300 meters of a busy roadway. In fact, McConnell et al. (2006) reported that the effect of the freeway on asthma was only seen in long term residents living within 75 meters of the roadway. Furthermore, this risk was not seen in boys for unknown reasons and suggests a weak association. Kan et al. (2008) noted that the contribution of ultrafine PM from highway traffic becomes indistinguishable from background concentrations at distances >300 meters. These observations are not consistent with CARB health risk assessments claiming increased health risks at increased distances from a railyard. As discussed previously, the CARB assessments were not based on actual air monitoring data showing that air contaminants were elevated at increased distances from a railyard facility. The above studies indicate that it is not plausible to assume that railyard activities would result in increased airborne chemical concentrations (and associated health effects) far off-site.

In terms of respiratory effects and their relationship to vehicular traffic, it is noted that a relationship has not been consistently identified. In fact, one of the studies cited by Ms. Hricko (i.e., Oftedal et al, 2009) notes that a causal relationship between long term exposure to traffic and asthma is so far not clear. In their study of asthma and association with traffic-related exposures they concluded: "We were not able to find positive associations of long-term traffic-related exposures with asthma onset or with current respiratory symptoms in 9- to 10-year-old children in Oslo." They further note that "Thus it is not clear whether air pollution can induce development of asthma, and we speculate that higher levels of exposure than was present in Oslo may be needed."

Specific exposures noted in some of the studies cited by Ms. Hricko as having health effects also do not appear relevant to the proposed intermodal facility. Gilliland et al. (2001) examined school absenteeism in Southern California children and attributed an effect primarily to ozone. Effects of NO_2 on school absenteeism were not observed at the levels measured in the communities. The authors further noted that "little evidence exists that symptoms from NO_2 exposure result in school absences." Ozone has not been specifically identified as a significant substance of concern for the intermodal facility. Wilhelm and Ritz (2005) and Salam et al. (2005) reported an association between carbon monoxide levels and either preterm birth and low birth weights. Carbon monoxide has not been specifically identified as a significant substance of concern for the intermodal facility. High levels of carbon monoxide are not typically associated with diesel engines in comparison to gasoline engines.

Several studies were cited regarding a possible association of air contaminants or other factors with cardiovascular disease. Babisch et al. (2005) was listed in relation to a possible association between traffic noise and myocardial infarctions in Berlin residents. Although an odds ratio of 1.3 for men exposed to sound levels more than 70 decibels during the day was reported, it was not statistically significant. Men who had lived in the area for at least 10 years had a slightly increased risk. However, such a risk was not seen in women which makes the association questionable. Regardless, evidence that the facility would result in noise exposure to this degree in residents living remote from the facility was not presented.

An animal study regarding exposure to ultrafine particles and the occurrence of early atherosclerotic lesions was cited (Araujo et al., 2008). However, it was noted that the exposures in this study were at levels 2-6 times higher than those typically experienced by commuters on Los Angeles freeways. Hartz et al. (2008) was also cited in support of a cardiovascular effect. The study involved direct exposure of brain capillaries from killed rats to diesel exhaust particles and has little practical relevance.

Pope et al. (2004) was cited as evidence of increased cardiovascular mortality due to exposure to fine PM. In the study, the authors reported that a 10 $\mu g/m^3$ increase in fine PM averaged over several years was associated with an 8-18% increase in cardiovascular mortality risk. No evidence was presented that the proposed BNSF intermodal facility would result in PM increases of this magnitude off-site. Similarly, Kunzli et al. (2005) examined atherosclerosis among Los Angeles residents and noted the annual mean $PM_{2.5}$ was 20.3 µg/m3. Kan et al. (2008) reported a small increase in coronary heart disease for individuals living within 300 meters of major roads compared with those living further away (i.e., hazard ratio of 1.12) but was not statistically significant. As noted above, they found that ultrafine PM levels from highway traffic became indistinguishable from background concentrations at distances >300 meters.

Lucking et al. (2008) and Mills et al. (2007) were cited as evidence of a cardiovascular effect. In these studies, volunteers were exposed to relatively high concentrations of diesel exhaust (300-350 $\mu g/m^3$) for an hour and blood clotting characteristics subsequently examined. No evidence was presented that the proposed intermodal facility would result in diesel exhaust exposures of this magnitude. As noted above, community diesel exhaust exposures estimated in the CARB studies were orders of magnitude lower than those examined in the Lucking and Mills studies.

In summary, studies cited in the respondent's comments have limited, if any, applicability to the proposed facility based on the circumstances of the studies, levels of exposure, and/or examined substances.

SUMMARY

- Exposure to sufficient levels of diesel exhaust in air may cause irritant and other symptoms. These symptoms are transient and resolve quickly when removed from the source of exposure.
- It is unlikely that diesel exhaust levels in air would be at concentrations sufficient to cause either acute or chronic non-cancer health effects as evidenced by CARB risk assessments which used extremely conservative exposure assumptions.
- Diesel exhaust is not a known cause of cancer.
- Studies which have reported an association between diesel exhaust exposure and lung cancer are difficult to interpret due to weak associations, limitations in exposure assessment, and inability to control for the effects of cigarette smoking.
- Diesel exhaust exposure levels in occupational studies reporting an association with lung cancer are not comparable to those which would occur at a remote location from the source. Airborne chemical concentrations decrease rapidly with increasing distance from the source.
- Studies cited by respondents regarding potential health effects of the facility have limited, if any, applicability based on the circumstances of the studies, levels of exposure, and/or examined substances.

Sincerely,

Table of Contents

Glossary of Terms

µm	Micrometer. One millionth of a meter
Background concentration	Concentration of substance in the absence of any significant sources present in the vicinity.
BC	Black Carbon
CARB	California Air Resources Board
CNG	Compressed Natural Gas
CO	Carbon Monoxide
CPC	Condensation Particle Counter
D_a	Aerodynamic diameter
DMA	differential mobility analyzer
D_P	electric mobility diameter
D_s	Stokes diameter
EC	Elemental Carbon
ELPI™	Electrical Low Pressure Impactor
EPA	Environmental Protection Agency
EU	European Union
Exposure	Contact with a substance by swallowing, breathing, or touching the skin or eyes
FMPS™	Fast Mobility Particle Sizer
I/O	Indoor to Outdoor
LA	Los Angeles
LPG	Liquefied Petroleum Gas
Mass Concentration	Total mass of particles in a unit volume of ambient air. Generally expressed as micrograms per m3
MATES	Multiple Air Toxic Exposure Study
nm	Nanometer. One billionth of a meter.
Number Concentration	Number of particles in a unit volume of ambient air. Generally expressed as number per m3 or number per cm3
OM	Organic Matter
Particle Size Distribution	Characterization of particle properties such as number or mass on basis of the particle size

PM	Particulate Matter
PM10	Particles with aerodynamic diameter less than 10 microns
PM2.5	Particles with aerodynamic diameter less than 2.5 microns
PMP	Particle Measurement Program
RIT	Road-induced Turbulence
SCAQMD	South Coast Air Quality Management District
SEM	Scanning Electron Microscopy
SMPS™	Scanning Mobility Particle Sizer
SO_2	Sulfur Dioxide
SULEV	Super Ultra Low Emissions Vehicle
TEM	Transmission Electron Microscopy
UFP	Ultrafine Particles
Ultrafine particle	Particles generally with aerodynamic diameter less than 0.1 micrometer
UNECE	United Nations Economic Commission for Europe
VIT	Vehicle-induced Turbulence

1. Introduction

Ambient particulate matter (PM) has been linked to numerous adverse health outcomes and remains a major environmental challenge. In recent years, there is increasing evidence of particle size playing a major role in determining the extent of adverse health effects. It has been observed that smaller particles have a higher probability of penetrating into and depositing in lower parts of the human lung and entering the bloodstream than larger particles, which are removed more efficiently by the defense mechanism of the mucociliary system (Daigle et al. 2003). Furthermore, on a mass basis, ultrafine particles have larger surface area and higher oxidant capacity than larger particles. This larger surface area likely enhances the toxic properties of the ultrafine particles. Animal studies in particular have shown increased pulmonary inflammation from ultrafine particles rather than larger particles with the same chemical composition. Therefore, there has been growing interest to better understand the particles in size range less than 100 nanometers (nm), commonly referred to as ultrafine particles.

Although the operational definition of ultrafine particles varies in the scientific literature, it is generally accepted that particles with size less than 100 nm (0.1 µm) are labeled as ultrafine particles. Note that the term nanoparticle is also used often in the scientific literature for particles with sizes on the order of few nanometers, especially in toxicological studies. Although this term is applicable to ambient particles with sizes less than 10 nm, it is applied more often to manufactured nanoparticles rather than those emitted due to human activities.

The health effects of concern from inhaling ultrafine particles include pulmonary inflammation, oxidative stress, and induction of exacerbation of cardiovascular disease (Peters, et al. 1997; Utell and Frampton 2000; Frampton 2001; and Murr and Garza 2009). There remains considerable uncertainty on biological mechanisms and the physiochemical components on the ultrafine particles that lead to these health effects. This remains a very active area of epidemiological research.

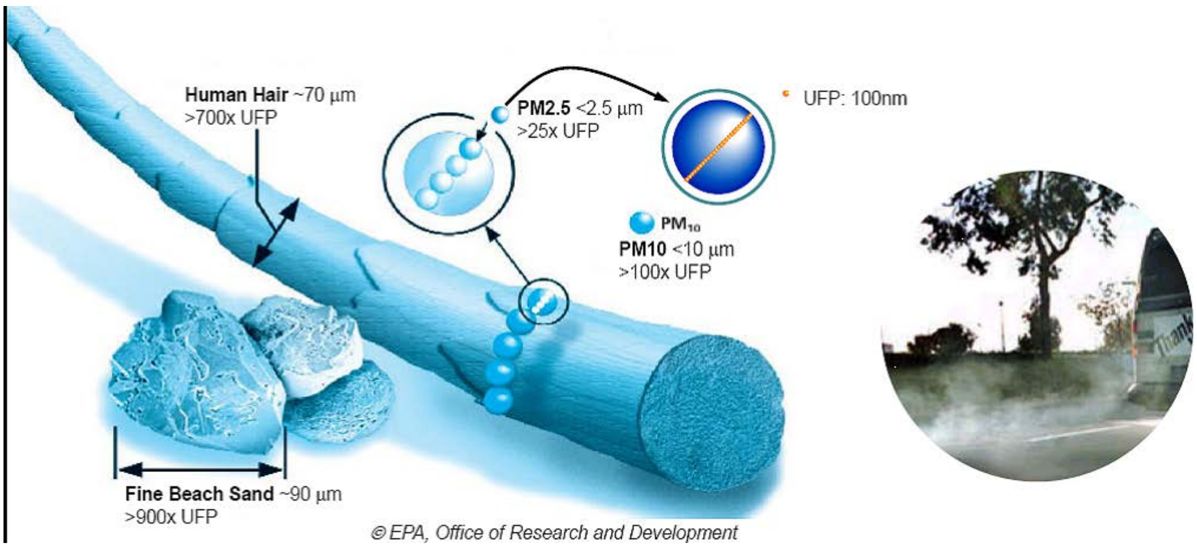
Despite a significant body of suggestive evidence linking ultrafine particles to adverse health effects, there are still many gaps in the knowledge of ultrafine particles to which people are exposed to in the environment. Areas continuing research to improve the understanding of exposure to ultrafine particles include understanding the behavior of the ultrafine particles in the near field and the atmospheric processing of these particles; developing robust measurement techniques and instrumentation; and developing operational protocols to accurately characterize them. The objective is to ultimately advise the public, the environment regulatory community, and other stakeholders in developing effective approaches that reduce exposure to ultrafine particles.

This report is prepared to briefly summarize the latest understanding of ultrafine particles in the context of the Gateway Cities Air Quality Action Plan and is organized as follows. Section 2 describes the characteristics of ultrafine particles and current techniques to measure their ambient concentrations. Section 3 describes emissions and mechanisms of the atmospheric processing of ultrafine particles emitted from vehicle tailpipes. Section 4 summarizes recent monitoring studies performed in the Los Angeles (LA) air basin, identifies major trends, and also presents studies that measure exposure to ultrafine particles in the LA air basin. Section 5 discusses current and prospects for future regulation of ultrafine particles. Finally, Section 6 concludes with a summary of major findings.

2. Characterization of Ultrafine Particles

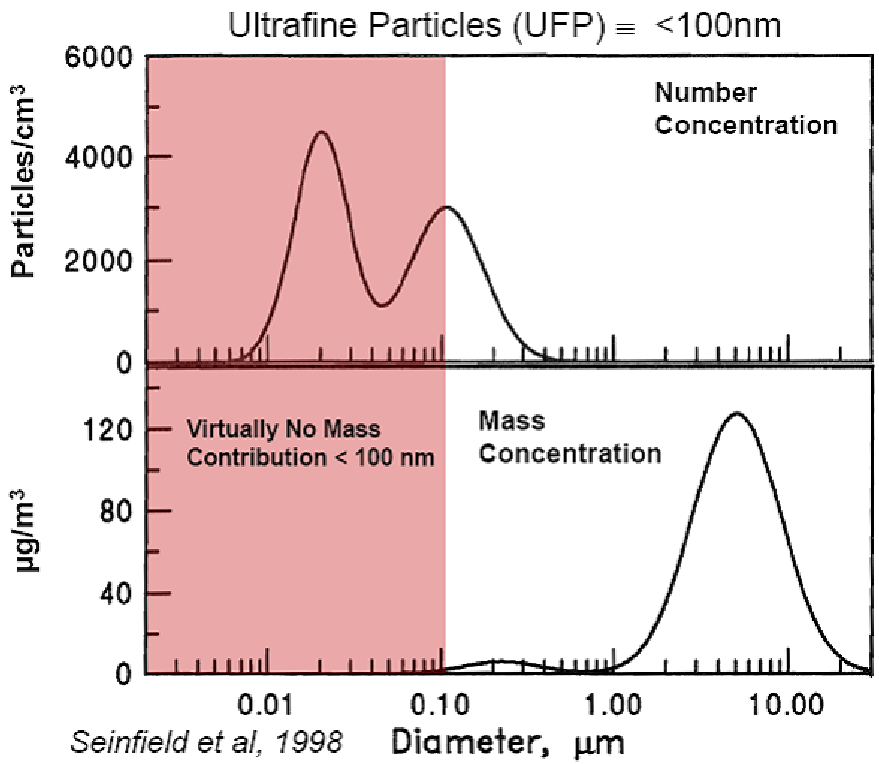
Ambient particles in general are characterized by their size, shape, physical properties (e.g., density, volatility), and chemical composition. For ultrafine particles, the most defining property is their size. As mentioned earlier, ultrafine particles are generally defined as particles with a diameter less than 100 nanometers (nm) or 0.1 micrometers (µm). In contrast, PM2.5 and PM10 consists of particles with diameters less than 2.5 and 10 µm, respectively. Therefore, ultrafine particles are nearly 25 times smaller than PM2.5 and 100 times smaller than PM10 in diameter. Figure 1 illustrates size difference between ultrafine particles, PM2.5, and PM10. Note that PM2.5 and PM10 fractions of the ambient PM also include ultrafine particles based on the above definitions. Currently, the mass concentration of PM2.5 and PM10 are regulated by national and California ambient air quality standards and, for motor vehicles, a mass per mile exhaust emission standard.

Figure 1. Relative Size of Ultrafine Particle (UFP) Relative to Human Hair and Other Particle Sizes



Because of their small size and volume, the aggregate mass of ambient ultrafine particles is not significant compared to larger particles. However, several studies have shown that ultrafine particles dominate the number concentration of ambient PM. For example, Stanier, et al. (2004) showed that 25% of the ambient aerosol particles are less than 10 nm and 75% of the number of particles are less than 50 nm. In contrast, particles larger than 100 nm, i.e. PM2.5 and PM10, primarily contribute to the mass concentration. See Figure 2.

Figure 2. Comparison of Number and Mass Distribution of Ambient Particles



Along with size, chemical composition also influences the toxicity of ultrafine particles. However, the chemical composition of ultrafine particles is even less well understood. This is mainly because a significant variation in chemical composition can be found within various environments, times of the day, and months of the year, depending on the nature and emission strengths of local sources and atmospheric conditions. Organic matter (OM), elemental carbon (EC), and inorganic compounds such as sulfates and nitrates constitute most of the ultrafine particle mass. Other constituents include water, sodium, potassium, and transition metals. EC is considered as a marker of the combustion processes for diesel engines as its major source in urban areas. OM, a mixture of high molecular weight hydrocarbons, is emitted directly from combustion processes and also forms in the atmosphere from gas-phase emissions. OM constitutes a significant fraction of emissions from meat cooking and wood burning. Sulfate in the particles results from sulfur present in the fuel that is oxidized during the combustion process. Similarly, high temperatures during combustion lead to the oxidation of atmospheric nitrogen, which results in presence of nitrates in ambient particles. Some recent studies conducted in southern California region showed that the chemical composition of ultrafine particles ranged from 32 to 69% of OM, 1 to 34% of EC, 0 to 24% of sulfate, and 0 to 4% of nitrate (Sardar et al. 2005; Arhami, et al. 2009).

The United States and California air quality standards for particulate matter are based on mass concentration. Therefore, currently there is no large-scale monitoring network that measures number concentration of ambient particles. Several studies are available in the literature that measured particle number concentration in various outdoor environments. Morawska et al. (Morawska, Ristovski et al. 2008) analyzed 71 measurement studies recently reported in the literature and calculated the mean and median number concentration for eight different environments. As shown in Table 1, the number concentrations are highest in tunnel environments followed by on road and roadside environments. The mean concentrations for these environments are greater by 64, 27, and 18 times respectively than a clean background.

Table 1. Mean and Median of Particle Number Concentrations in Various Environments

Environment	Mean (10^3 Particles/cm)	Median (10^3 Particles/cm)
Tunnel	167.74 (64)	99.09 (31)
On Road	71.45 (27)	47 (15)
Roadside	48.18 (18)	34.58 (11)
Street Canyon	42.07 (16)	39.13 (12)
Urban	10.76 (4)	8.83 (3)
Urban background	7.29 (3)	8.1 (3)
Rural	4.83 (2)	2.91 (1)
Clean Background	2.61 (1)	3.2 (1)
Data source: Morawska et. al. 2008. The numbers in parenthesis show the ratio of the concentration statistic with that of a clean environment.		

2.1. Measurement of Ultrafine Particles

Ambient particles often have variety of shapes (e.g. tubular, irregular, etc.) rather than ideal spherical shape, which can be characterized by only one size parameter (the diameter). Therefore, this poses some difficulties in their mass and number concentration measurement. Aerodynamic diameter (D_a), Stokes diameter (D_s), and electric mobility diameter (D_P) equivalent are often used in the context of the properties of particles moving in air. Aerodynamic diameter is the diameter of a perfect sphere of unit density with same mobility as the particle being measured. Stokes diameter is similar to the aerodynamic diameter, but uses the true density of the particle. Electric mobility diameter is widely used in instruments and defined as the diameter of a perfect sphere of unit density with same electric mobility as the particle being measured.

A recent review by Kumar, et al. (2010) identified several instruments that are commercially available to measure the size distribution of ambient particles, including ultrafine particles. These instruments include the Scanning Mobility Particle Sizer (SPMS™), Fast Mobility Particle Sizer (FMPS™), and Electrical Low Pressure Impactor (ELPI™) that provide size-segregated number concentration. In addition, a condensation particle counter (CPC) is a standard instrument employed in the study of ultrafines to provide number concentration of the entire aerosol population.

The SMPS system is an instrument that uses electric mobility principles to measure the number and size distribution of an inlet aerosol population Kumar, et al. (2010). This instrument mainly consists of three components: 1) A bipolar radioactive charger to charge the particles, 2) a differential mobility analyzer (DMA) to classify the particles based on their electrical mobility, which in turn depends on their size, and 3) a CPC for detecting the particles and providing the number concentration. Some commercially available SMPS include the 3034 TSI (TSI Inc) that measures D_p between 10 and 487 nm for number concentrations in the range of 10^2 to 10^7 particles/cm^3 and takes 180 seconds to analyze a single scan. More recent models (such as the 3934 TSI) can measure a larger range of particle size and with shorter sampling times (30 seconds).

The FMPS is similar to SMPS in principle. However, instead of a CPC, the FMPS uses multiple, low-noise electrometers for particle detection and count. The main advantage of FMPS is that its sampling frequency can be as high as 1 Hz (i.e., analysis of one sample per second), which is partly accomplished by using a high sample flow rate. Therefore, FMPS can be used to characterize fast-changing particle populations.

The ELPI is another instrument that has high sampling rates and measures the size distribution of particles in the range of 30 to 10,000 nm. This instrument uses aerodynamic size classification of charged particles by a low pressure cascade impactor and subsequent electrical detection for particle count. An added advantage of this instrument is that the cascade system allows for other analysis such as chemical composition and further characterization through scanning electron microscopy (SEM) or transmission electron microscopy (TEM) techniques.

As noted by Kumar et al. (2010) several parameters need to be considered before adopting a particular instrument or detection technique to be used in a regulatory or compliance context. These include portability, time response, detection limits, sampling frequency, reproducibility and capability of unattended operation over long duration, and cost and maintenance requirements. Despite technological advancements in recent years that address many of these issues, reproducibility and consistency across various instruments still remains an area that needs additional research and progress. Asbach et al. (2009) used four different particle sizers (two TSI SMPS, one TSI FMPS, and one Grimm SMPS) to analyze NaCl and diesel soot particles and found that each instrument showed repeatable results. However, there was a considerable difference between instruments. Among these four instruments, FMPS consistently showed lower particle size distributions than SMPS.

3. Ultrafine Particles in Near-Roadway Environment

Several studies have shown that motor vehicles are the dominant source of ultrafine particles in the outdoor environment. Furthermore, the concentrations are highest in the near-roadway locations given their proximity to the emission sources. Among motor vehicles, heavy duty diesel engines are shown to emit significantly higher numbers of ultrafine particles than light-duty gasoline vehicles. In general, a heavy duty diesel truck or a bus may emit one or two orders of magnitude higher than a typical light-duty vehicle (Kirchstetter, et al. 1999; Ristovski, et al. 2005).

The number concentration of ultrafine particles at a near-roadway location is primarily determined by the strength of emissions in the surrounding area and atmospheric processing of the emitted particles as they are transported to the location of interest. These two aspects are discussed further below.

3.1. Emissions of Ultrafine Particles from Vehicles

From emissions perspective, ultrafine particles can be classified into either *primary* or *secondary* particles. Primary particles are formed in the engine and tailpipe and are emitted directly into the ambient atmosphere. These particles, mostly agglomerates of solid-phase carbonaceous material, are generally in the size range 30 to 500 nm. As hot gases are released from the tailpipe, they are cooled rapidly in the ambient environment. Consequently, many of the constituent gases with low-volatility condense to form a large number of new particles. These are known as secondary particles and are generally below 30 nm. Secondary particles are largely composed of sulfate, nitrate, ammonium, and organic material.

The first step in quantifying and addressing the extent of vehicle emission contribution to the ambient concentration is characterization of the tailpipe emissions and how such emissions vary with the nature of fuel composition, operating conditions, and control technologies.

Early studies on particulate emissions and fuel composition focused on sulfur content. Sulfur occurs naturally in crude oil and is mostly removed in the refining process, but a small percentage remains in diesel and gasoline fuel. During the combustion, sulfur is oxidized to sulfuric acid and is emitted through exhaust as a volatile material. After leaving the tailpipe, sulfuric acid undergoes condensation or nucleation and contributes to total particle emissions. Dynamometer and on-road measurements have shown that particle number decreases with the sulfur content both in fuel and lubricants. The introduction of ultra low sulfur fuels in California in 2006 and fully phased in nationwide by 2010 has significantly reduced ultrafine particles forming from sulfur condensation and nucleation.

In recent years, various biofuels (both pure and blended) have begun to be used in heavy duty diesel trucks and buses in order to decrease the reliance on imported fossil fuels and also to mitigate climate change. This transition may affect tailpipe emissions. Studies have shown that most heavy duty vehicles powered by biofuels emit a higher number of particles than those powered by diesel (Kumar, et al. 2010). This increase is attributed to the increased nucleation rates in the exhaust of biofuels due to reduced surface area of pre-existing particles and lower caloric content in biofuels requiring the use of greater quantities of fuel compared to conventional diesel fuel. However, it is important to note that the use of biofuels leads to overall reduction in particulate mass emissions due to the decrease in the emissions of solid carbonaceous particles.

Among alternative fuels, liquefied petroleum gas (LPG) and compressed natural gas (CNG) are seen as cleaner than conventional diesel or biofuels and are widely used in the South Coast bus fleet, and they have potential as a widespread replacement fuel for heavy duty trucks. A few studies that have examined these fuels have found that LPG vehicles are shown to emit 70% less ultrafine particles than conventional unleaded gasoline vehicles (Ristovski, et al. 2005). CNG vehicles are known to emit considerably less particle mass than diesel vehicles. Although CNG and LNG buses emit lower number of particles at lower loads compared to diesel buses, both dynamometer and on-road studies have shown that the number of particles emitted by CNG at high loads and during acceleration are an order of magnitude greater than those of diesel buses (Jayaratne, et al. 2010). For CNG buses, emissions of particle number vary by an order of magnitude between low-load and high-load conditions.

As with other vehicle emissions, ultrafine particle emissions from tailpipes may be controlled using the after-treatment devices. Two main classes of these devices are oxidation catalysts and particle traps. Oxidation catalysts mainly remove the soluble organic fraction and have no effect on elemental carbon in the exhaust. Further, these catalysts may oxidize sulfur dioxide (SO_2) to sulfate and may increase sulfate in particle mass and number. Therefore, the effectiveness of these devices depends on the relative chemical composition of the exhaust. Application of oxidation catalysts may actually increase the particle number when used in conjunction with high sulfur-content fuels (Vogt, et al. 2003).

Particle traps have proven to be effective in removing the solid-phase particles, including elemental carbon. However, volatile material (in gas or liquid form at high exhaust temperatures), especially sulfate mass, passes through the filter and acts as a precursor to nucleation-mode particles. Furthermore, by retaining solid-phase particles, particle filters may promote nucleation over condensation thus leading to an increase in the formation of new particles.

3.2. Environmental Fate and Transport of Ultrafine Particles

Almost immediately after the ultrafine particles are emitted into the atmosphere, atmospheric processes govern their fate and transport in the ambient environment and dynamically change their physical and chemical characteristics. Consequently, the temporal and spatial evolution of ultrafine particles, especially their size distribution, depend on the extent of atmospheric processing, which in turn depends on ambient meteorological conditions such as temperature, wind speed, relative humidity, and incident solar radiation.

Once particles are emitted from the vehicle tailpipe, transport by wind is the main mechanism by which emissions are initially dispersed into the atmosphere, resulting in dilution of the exhaust plumes. Turbulent transport, both in the horizontal and vertical direction, dominates the dispersion of pollutants. In general, high wind speeds result in efficient transport of pollutants, leading to lower ambient concentration in the vicinity of emissions sources. Atmospheric stability, a measure of resistance to the vertical motion of air parcels in the atmosphere,[1] also significantly affects the turbulent mixing and resulting dispersion of emissions.

Another distinguishing feature between the dispersion of pollutants from roadway and non-roadway sources is the effect of turbulence generated by vehicles, roadway structures, and noise barriers. The near-roadway turbulence, broadly classified into vehicle-induced turbulence (VIT) and roadway-induced turbulence (RIT), may significantly contribute to the mixing of pollutants, leading to additional dilution of near-roadway emissions (Bäumer, et al. 2005; Kalthoff, et al. 2005). A significant fraction of kinetic energy may be converted into additional turbulence due to the aerodynamic resistance when fast-moving vehicles interact with the ambient air. The turbulence generated strongly depends on the vehicle shape and speed. For example, heavy duty diesel trucks induce more turbulence due to their size and shape than passenger cars. Therefore, reducing congestion and increasing speeds will promote more mixing and lower peak concentration of ultrafine particles.

Road embankments also generate turbulence as they act as the obstacle to the wind flow. The RIT due to embankment depends on the wind speed, direction, and the height and shape of the embankments. Similarly, roadside structures such as noise barriers and vegetation also affect dispersion by creating local turbulence effects (Lidman 1985; Baldauf, Thoma et al. 2008). In addition, the temperature difference between asphalted roadway surfaces and surrounding grassy surfaces creates thermally induced flow, which could affect dispersion of roadway emissions. Finally, in an urban environment, built structures distort the wind field around them and therefore affect the dispersion of pollutants.

Zhang and Wexler (2004); Zhang, et al. (2004); and Zhang, et al. (2005) proposed that the dilution of a vehicle exhaust plume may be considered to occur in two distinct stages. The first is the tailpipe-to-road dilution by the strong turbulence generated by traffic, lasting about 1 to 3 seconds and causing the initial concentration of ultrafine particles to be diluted by up to a factor of 1,000. The second stage is the roadway-to-ambient environment, which further dilutes the concentration of ultrafine particles by about a factor of 10, lasting 3 to 10 minutes. This dilution is due to atmospheric turbulence and advection by the ambient wind. Such large dilution ratios lead to an exponential decrease in the number concentration of ultrafine particles within relatively short distances from a freeway as observed in a number of studies (Zhu, et al. 2002a; Westerdahl, et al. 2005; Morawska, et al. 2008).

As vehicle exhaust plumes are diluted in the atmosphere, three main processes—nucleation, condensation, and coagulation—change the size of the particles in the plume and govern the overall size distribution. Nucleation refers to the formation of new particles with a size generally below 20 nm from super-saturation of low volatility gaseous compounds. However, such super-saturated compounds can also condense onto pre-existing particles, which increases the size of such particles. Thus, nucleation and condensation are two competing processes. The availability of a pre-existing particle surface area

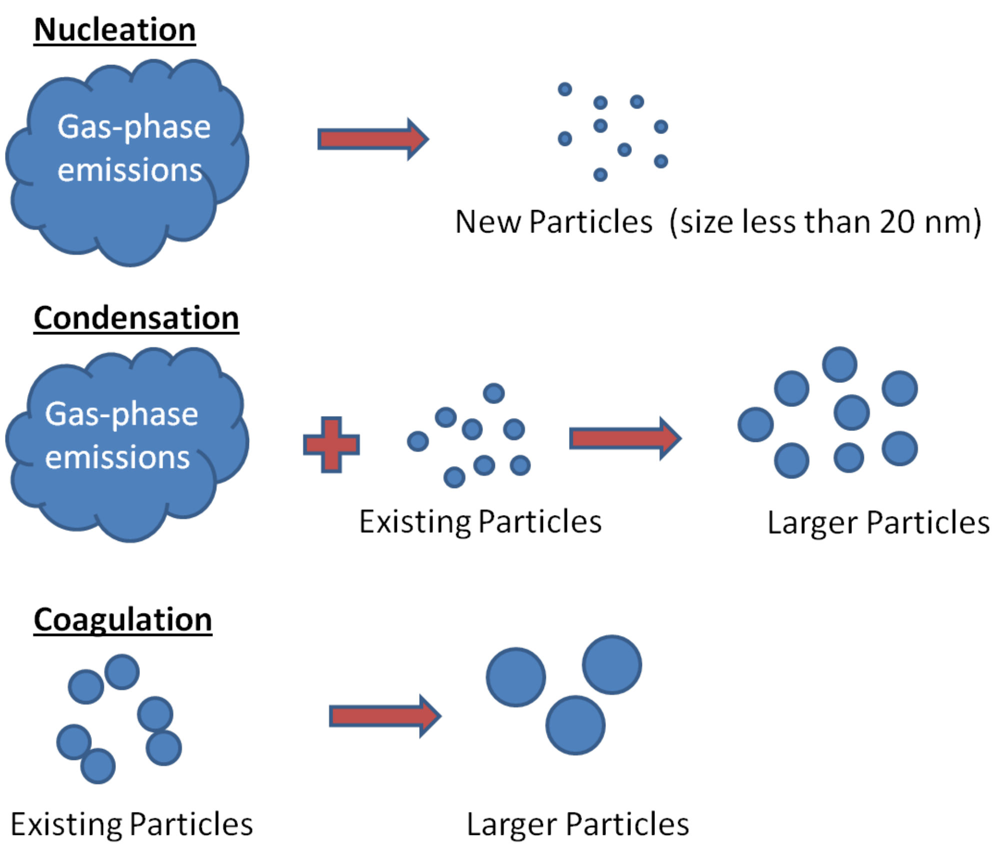
[1] Stability can be broadly classified as stable, neutral, and unstable. Stable atmospheric conditions restrict the vertical movement of air parcels, thus creating conditions conducive for the accumulation of pollutants near the surface. Unstable atmospheric conditions accelerate the vertical movement of air parcels and promote the turbulent mixing of pollutants. Under neutral conditions, the dispersion of pollutants is influenced by both transport and turbulent mixing.

and plume dilution rate determines which of these processes dominates. Polluted urban environments often contain a large number of pre-existing particles to favor condensation over the formation of new particles through nucleation. Coagulation occurs when two or more particles collide and combine to form a new larger particle. Figure 3 graphically illustrates these three processes.

The emissions from the tailpipe of a vehicle containing highly concentrated gas vapors undergoes rapid cooling immediately after leaving the tailpipe, during the tailpipe-to-road dilution phase, and reaches super-saturation, which may result in both the generation of new particles through nucleation and growth of the existing particles through condensation. Such particles, often less than 30 nm in size, have been observed near busy freeways, especially those carrying a large fraction of heavy duty diesel trucks (Zhu, et al. 2002b; Westerdahl, et al. 2005; Ntziachristos, et al. 2007).

The rate of generation of ultrafine particles depends on several factors, including temperature, relative humidity, atmospheric stability, and vapor pressure (Zhang and Wexler 2004; Zhang, et al. 2005). Low ambient air temperatures and high relative humidity favors the formation of new particles as demonstrated in some on-road studies (Ronkko, et al. 2006; Casati et al. 2007). Particles that are generated through nucleation have short atmospheric lifetimes, on the scale of few minutes, because they coagulate with other particles and form new larger particles.

Figure 3. Illustration of Nucleation, Condensation, and Coagulation Processes That Affect the Size Distribution of Ambient Particles



4. Ambient Concentration of Ultrafine Particles in the Los Angeles Area

As the significance of ultrafine particles' possible public health concerns have gained increasing attention in recent years, several monitoring studies have been performed, mostly by academic institutions, to better characterize and understand the ambient concentrations of ultrafine particles, especially in near-roadway environments. This section synthesizes the trends and characteristics of ambient ultrafine particles reported in the scientific literature drawn from studies conducted in the Los Angeles area.

As discussed in the previous section, a distinguishing feature of ultrafine particles is their elevated concentration close to roadways (or emission sources) and their exponential decay with distance from the freeway because of transport and turbulent mixing. This behavior has been confirmed in several field studies conducted in the vicinity of a number of southern California freeways.

Zhu, Hinds et al. (2002a; 2002b) conducted four measurement campaigns to characterize the ultrafine particles in LA area during the summer of 2001 and the winter of 2002. These studies measured the particle number concentration and size distribution in the size range from 6 to 220 nm at various distances from I-405 and I-710. In addition, the mass concentrations of carbon monoxide (CO) and black carbon (BC) were also measured at each sampling location. Black carbon is a close surrogate for diesel PM emissions. Since an identical set of instruments was used and common data analysis methods were applied by the same group of researchers, the bias in configuration and data interpretation is minimized. Therefore, data from these studies can be used to obtain important insights and understanding of ultrafine particle characteristics in the near-roadway environment.

The summertime measurements were conducted 30, 60, 90, 150, and 300 meters downwind and 300 meters upwind for I-405 at the Los Angeles National Cemetery between May 15 and July 18, 2001. For the I-710 study, the measurements were taken at 17, 20, 30, 90, 150, and 300 meters downwind and 200 meters upwind from the freeway in the City of South Gate along Southern Avenue between August 30 and October 27, 2001. Wintertime measurements were taken at the same monitoring sites between January 11 to January 20, 2002, for the I-405 sampling sites and between January 14 and January 25, 2002, for I-710 sampling sites. For all studies, particle measurements were made using a CPC for total number concentration (CPC 3022A; TSI Inc.) and SMPS for size-segregated number concentration (SMPS 3936, TSI Inc.).

The traffic on I-405 is dominated by passenger cars and light-duty vehicles with less than 5% of heavy-duty diesel trucks. In contrast, the heavy-duty diesel traffic on I-710 is often higher than 25%. During the measurement period, the hourly average traffic volume on I-405 was 13,900 vehicles, and more than 93% of these were gasoline-powered passenger cars. A strong correlation was observed between the traffic density and measured total particle concentration for monitoring sites near I-405. For the I-710 study, the hourly average hourly traffic volume was 12, 180 vehicles with heavy trucks constituting nearly 30%. The traffic density during this study has less variation than that of I-405.

As discussed in the previous section, wind plays a major role in the dispersion of emitted ultrafine particles. Due to frequent on-shore winds, the monitoring sites in both studies by Zhu et al. (2002a, 2002b) were downwind of the freeway 80% of the time. Total particle number concentration measured by a CPC located 30 meters downwind from I-405 decreased almost linearly with the wind speed with a correlation coefficient (R^2) value of 0.99. In contrast to this behavior, total particle concentration first increased with the wind speed up to 1.5 m/s and then decreased. This anomaly was attributed to large uncertainty in measurements made when speeds are less than 1 m/s.

The findings from Zhu have important implications for I-710. Prevailing winds along the I-710 corridor in the AQAP study area are from the southeast to east. This will typically lead to the highest ultrafine particle exposure over the Los Angeles River south of State Route 90 (Imperial Highway) where the nearest sensitive receptors on the east side of the I-710 are more than 500 meters from the roadway. North of the State Route 90, where the Los Angeles River is to the west of I-710, the communities of Bell Gardens, Commerce, and East Los Angeles are in much closer proximity to I-710 and are in the prevailing downwind direction.

Despite the difference in the traffic vehicle mix, both studies by Zhu showed some common behaviors. The maximum number concentration that was observed next to I-710 and I-405 is nearly 25 and 30 times that of the background concentration, respectively. However, the number concentration of ultrafine particles near both freeways falls precipitously with the distance and become indistinguishable from an upwind site at 300 meters. In addition, the CO and BC concentrations also decrease at the same rate as particle number in both studies and drop by 60 to 80% within first 100 meters. However, PM mass concentration, measured in the I-405 study decay at a much smaller rate, displays different characteristics from CO, BC and particle number concentrations. This is because direct PM emissions from passenger car emissions contribute a relatively small amount relative to background PM concentration. The CO, BC, and number concentration data is summarized in Tables 2 and 3.

Both studies by Zhu (2002a and 2002b) also analyzed the evolution of size distribution of ultrafine particles in a near-roadway environment using the data collected from SMPS. The size distribution of ultrafine particles sampled at both I-405 and I-710 showed three distinct modes. Zhu (2002b) further examined the number concentration of particles in the following size bins: 6 to 25 nm, 25 to 50 nm, 50 to 100 nm, and 100 to 220 nm. In both studies, the particles in the smallest bin (6 to 25 nm), contribute over 70% to the total number concentration and decrease sharply within first 100 meters from the freeway. This characteristic is attributed to the rate of coagulation and faster diffusion rates of smaller particles.

Table 2. Measured Average Concentrations of Ultrafine Particles, CO and BC at Increasing Distances from I-405

Measurement (m)	30	60	90	150	300
CO (ppm)	2.0 (1.7-2.2)	0.9 (0.7-1.0)	0.6 (0.5-0.7)	0.4 (0.3-0.5)	0.2 (0.1-0.3)
BC (µg/m³)	5.4 (3.4-10.0)	3.2 (3.0-3.5)	2.5 (2.4-2.6)	1.6 (1.1-2.0)	1.3 (1.1-1.5)
Number Concentration (x10⁵/cm³)	1.5 (1.3-1.7)	0.88 (0.77-0.96)	0.70 (0.61-0.85)	0.50 (0.42-0.58)	0.37 (0.30-0.39)
Data Source: Zhu 2002a, 2002b. Range given in parenthesis. Note these concentration include background.					

Table 3. Measured Average Concentrations of Ultrafine Particles, CO and BC at Increasing Distances from I-710

Measurement (m)	17	20	30	90	150	300
CO (ppm)	2.3 (1.9-2.6)	2.0 (1.5-2.4)	1.7 (1.1-1.9)	0.5 (0.2-0.7)	0.4 (0.1-0.5)	0.2 (0.1-0.3)
BC (µg/m³)	21.7 (20.3-24.8)	19.4 (16.5-21.6)	17.1 (12.6-19.3)	7.8 (4.5-9.3)	6.5 (3.9-9.2)	5.5 (3.5-7.7)
Number Concentration (x10⁵/cm³)	2.0 (1.8-2.5)	1.8 (1.5-2.5)	1.6 (1.2-1.9)	0.72 (0.42-1.1)	0.61 (0.35-0.98)	0.49 (0.30-0.59)
Data Source: Zhu 2002a, 2002b. Range given in parenthesis.						

Zhu (2002b) also compared the size-resolved number concentrations of ultrafine particles measured 30 meters from I-710 and I-405 freeways. Note that both freeways have nearly the same average traffic density; however, I-710 traffic emits higher levels of PM due to the greater proportion of heavy duty diesel trucks. Both sets of measurements showed three distinct modes. The number concentration close to I-405 for the first mode (10 and 20nm) is slightly higher than corresponding measurement at I-710. However, the concentration for the second mode (around 30 nm) is nearly 30% higher for the I-710 site than that of the I-405 site and is attributed to higher levels of BC particles emitted by diesel vehicles on I-710. The concentration of the last mode (around 70 nm) is similar in both studies and close to the background concentrations.

As discussed in the previous section, meteorological parameters such as temperature and relative humidity play a major role in the processing of ultrafine particles. A comparison of summer and wintertime monitoring data for the I-405 and I-710 sampling sites showed that ultrafine number concentrations in winter are higher than in summer for comparable level of traffic densities. In addition, the decay rates of ultrafine particles, CO, and BC are slightly smaller than those in summer. This decrease in the dilution rate is attributed to the prevailing lower wind speeds during winter. When the size-segregated data was compared, the mode with the smallest diameter (10 to 20 nm) persisted for longer distance during the winter season.

More recent studies have employed mobile measurement platforms to conduct more comprehensive data collection. As opposed to the studies that use a limited number of fixed monitoring locations, mobile platforms measure concentration at all directions from the road from a parallel to perpendicular direction along the roadway, but for generally shorter durations. Further, mobile measurements often also include video and audio recordings of the surroundings in order to infer possible pollution with specific sources, such as passing or following a diesel truck.

Kozawa et al. (Kozawa, Fruin et al. 2009) used an electric vehicle as a mobile measurement platform and collected measurements on two routes of about 30 miles each covering arterial roads in residential areas and freeways in the cities of Carson, San Pedro, Wilmington, and West Long Beach. Among other instruments to measure gas-phase species, the mobile platform also included a portable CPC (TSI Portable CPC, Model 3007) and FMPS (Model 3091, TSI), both having a time resolution of 10 seconds. The CPC was used to measure number concentration of particles in the range 10 nm to 1 µm and the FMPS to provide the size distribution and particles in the range of 5.6 to 560 nm.

Measurements in the Kozawa et al. study were collected by driving twice a day along the two routes, once in the morning between 8:00 and 10:30 AM and again in the afternoon between 14:30 and 17:00, two to three times per week in the summer and winter of 2007 covering a total of 24 sampling days. Since the goal of the study was to measure representative ambient concentrations, individual vehicle influences, such as a passing or trailing a high emitting diesel truck, were removed from the assessment based on the analysis of video recordings made during the measurements. Measured concentrations were analyzed using the “impact zone” and “reference zone” designations based on the location of the measurement and then calculating the ratio of concentration within the impact zone with that of the reference zone. Any location within 150 meters from a major roadway is designated to be within the impact zone. All other locations more than 150 meters from a major roadway are said to be in the reference zone. In addition, meteorological data from the South Coast Air Quality Management District (SCAQMD) monitoring station at North Long Beach were used to determine if the measurement locations are at a downwind or upwind of a major roadway.

Using the above approach, Kozawa et al. observed that the ratio of ultrafine number concentrations in the impact zone to the reference zone in the I-710 area to be at least 2 and as high as 3.7 times higher in the morning hours, and when the impact zone is downwind of the freeway. The impact- to reference-zone ratios were approximately 1 (or no change) when the impact zone was upwind of the freeway.

Near-roadway studies, such as those discussed above, often compare pollutant concentrations close to the freeway with those of “background” or reference concentrations. Background concentration is typically measured more than 300 meters downwind or upwind of the freeway. For community-scale exposure and impact assessments, the variation in the background concentration also becomes important, especially in order to devise air quality improvement strategies. Insights on neighborhood-scale variation of ultrafine particles, especially in communities that are in the vicinity of the major transportation routes, will provide insight as to whether to focus air quality improvement strategies on a broader or local/neighborhood scale.

Moore et al. (Moore, Krudysz et al. 2009) measured ambient ultrafine particles using a network of 14 closely-spaced monitoring sites that were set up in the Los Angeles area as two clusters—San Pedro/Wilmington and West Long Beach. At these sites, total number concentration of particles greater than 7 nm is measured using a CPC (3022A, TSI Inc.). The measurements were taken from February through December of 2007 in order to assess intra-community variability in the ambient ultrafine particle concentrations. A number of sites within the West Long Beach cluster are in the proximity of I-710 at varying distances. This study showed that the total particle number can vary up to a factor of 10 for sites within a few kilometers. Although the proximity to roadways was a major factor in the variability, the observations emphasize that urban areas have elevated concentrations relative to background levels and that ultrafine concentrations vary widely between communities due to proximity to roadway sources as well as other sources of ultrafine particles.

4.1. Exposure to Ultrafine Particles in Los Angeles Area

Human exposure may generally be defined as any event where a person comes in contact with a contaminant of concern. During an exposure event, the contaminant may enter the human body through one of the exposure pathways (or exposure routes). The main exposure pathways are inhalation, ingestion, and dermal absorption. Exposure to ultrafine particles predominantly occurs through the inhalation of polluted air.

People are exposed to ultrafine particles during the course of their daily activities depending on various microenvironments they spend time in, the amount of time spent, and the concentration of ultrafine particles in those microenvironments. A microenvironment is any space in which human contact with an environmental pollutant takes place and which can be treated as a well-characterized, relatively homogeneous location with respect to pollutant concentrations for a specified time period. Microenvironments are generally grouped into three categories: outdoor, indoor, and in-vehicle. For example, parks, outdoor recreation spaces, and near-roadway locations are some common outdoor microenvironments; residences, schools, and offices are some common indoor microenvironments; and cars, public transit vehicles, and air travel compartments are some common in-vehicle microenvironments.

In the context of near-roadway environment, two classes of populations that are most vulnerable to ultrafine particles exposure: 1) residents or occupants of non-residential buildings within in the vicinity of major roadways, and 2) drivers and passengers of on-road vehicles. The extent of exposure within these two microenvironments (home/office and in-vehicle) mainly depends on the air exchange rate that determines the extent of penetration of outdoor contaminated air into the microenvironment. Air exchange rates are governed by several factors such as ventilation and meteorological factors (wind speed).

Although exposure to gas-phase pollutants in a near-roadway environment is still a major research area, exposure specifically to ultrafine particles is gaining attention. A recent review published by Knibbs et al. (Knibbs, Cole-Hunter et al. 2011) identified 47 studies that reported numerical exposure values to ultrafine particles across various transportation modes. Based on this data, the trip-weighted mean ultrafine particle concentration near automobile tunnels was highest at 300,000 particles/cm^3 and that in a non-tunnel automobile trip was 45,100 particles/cm^3. By way of comparison with some typical indoor activities, Wilson et al (Wilson, A., O. Karpukhin, L. DeLaura, 2010) found that indoor concentrations of ultrafines during cooking meat, burning candles, and vacuuming ranged between 150,000 to 200,000 particles/cm^3.

In a recent study done by USC researchers (Hudda, Cheung, Moore, and Sioutas 2010), they found that the 2009 outdoor concentration at the University of Southern California site, which was located in an area believed to be representative of a typical urban background site, the highest ultrafine particle concentration occurred in January with an average concentration of 30,000 particles/cm^3 and the lowest ultrafine particle concentration of around 10,000 particles/cm^3 occurred during September. This is comparable to the background concentrations measured by Zhu et al. (2002a), which reported a background concentration of 30,000 particles/cm^3 at 300 meters, but the Zhu study was done in 2001 and ultrafine particle concentrations have shown a region-wide decrease across the South Coast region over this time period.

Two of the recently published studies on exposure to ultrafine particles in near-roadway environment in the LA basin are discussed here. Zhu, et al. 2005 concurrently measured ultrafine particle concentrations for four two-bedroom apartments located within 60 meters of the I-405 freeway. Three of these apartments are located on eastern side of the I-405 on the third floor. The fourth apartment is located on the western side of the I-405 on the second floor. All four apartments are within 50 meters of each other. Measurements were collected under three infiltration conditions: infiltration, mechanical ventilation, and with an open window. Size-segregated number concentration of ultrafine particles were measured using SMPS (3936, TSI Inc.) between October and January of 2003. Total particle number concentration was also measured independently using a particle counters (Model 8525, TSI Inc.) with a lower cut size of 20 nm. The penetration of ultrafine particles into residences is quantified using the ratio of Indoor to Outdoor (I/O) number concentrations of ultrafine particles. The I/O ratios are highest—close to 1.0—across all particle size ranges when the windows are open. Under the infiltration (natural ventilation) condition, the highest ratios (0.6 to 0.9) were observed for larger particles in the size range of 70 to 100 nm, while the lowest I/O ratios (0.1 to 0.4) occurred for particles in the size range of 10 to 20 nm. Finally, the lowest I/O ratios (0.2 to 0.6) occurred when the fan was on (mechanical ventilation) and is attributed partial filtering by the air-handling system in these apartments. The generally high I/O ratios indicate that residents in the vicinity of freeways are potentially exposed to ultrafine particles at levels similar to those in the outdoor air. Similar exposures would be anticipated along I-710 in close proximity and at the same elevation level as the roadway.

In addition to the exposure in indoor environments, in-vehicle exposure while driving on heavily-trafficked freeways is also shown to be significant. Zhu, et al. (2008) measured outdoor and in-vehicle particle number concentrations for three different vehicles (Volkswagen Jetta, Audi A4, and PT Cruiser) while driving on I-405 and I-710 in the LA area. Measurements were taken under three different air circulation conditions: 1) circulation fan off and recirculation off; 2) fan on and recirculation off; and 3) fan on and recirculation on. It is expected that outside air enters the vehicle only in conditions 1 and 2.

Results showed that the particle concentrations inside the vehicle closely tracked outside concentrations under conditions 1 and 2. I-710, with a high proportion of trucks and therefore a large number of ultrafine particle emissions, resulted in the highest in-vehicle ultrafine particle concentrations and therefore the highest exposure as well. The penetration ratio (ratio of indoor to outdoor particle concentrations) was highest when both the fan and recirculation are off and varied between 0.3 and 0.5. These ratios are similar for both the freeways. Overall, maximum protection was obtained when both the fan and recirculation were on. Further, based on the observations from this study, the authors concluded that the exposure to ultrafine particles from a 1-hour commute on busy LA freeways is equivalent to 10 hours of exposure in urban backgrounds away from a freeway.

5. Current and Prospects of Future Regulations on Ultrafine Particles

There are potentially two direct ways of regulating ultrafine particles: 1) by setting ambient standards, similar to that of PM mass per unit volume and other gas-phase pollutant standards, and 2) by regulating the tailpipe emissions, i.e., source-based regulation. Indirect ways of regulating ultrafine particles include restrictions on fuel composition.

Currently, there is no ambient air quality standard any place in the world that regulates the number concentration of airborne particles.

Until recently, there were no emission standards that regulated the particle number concentration from vehicle tailpipes. However, in July 2008, the UK Department of Transportation proposed an emissions standard for light and heavy duty compression (diesel) ignition vehicles at 6×10^{11} particles/km. These limits were agreed for inclusion in the European tailpipe standards for Euro-5 and Euro-6 emission standards. Euro-5 tailpipe particle number standards are being phased in starting in September 2011 and fully phased for all models by January 1, 2013. The test methodologies for the implementation of this standard were developed under the Particulate Measurement Program (PMP) of United Nations Economic Commission for Europe (UNECE). PMP, initiated in 2001, is an inter-governmental research program to develop new vehicle exhaust measurement protocols for regulatory applications. The PMP focuses on development of methodologies to measure solid particles in the range 23 to 2500 nm. Per the PMP test procedure, only solid particles are counted towards the emission standard since any volatile material is removed from the sample. The US Environmental Protection Agency (EPA) has reviewed the PMP testing method and does not see this as an acceptable approach for the US partly because of the missing volatile material.

The EPA has no immediate plans to regulate ultrafine particles. However, there is increasing interest within the EPA in researching investments directed towards the understanding of ultrafine particles and their significance relative to fine particles (PM2.5) and their role in causing adverse health effects. To address these questions, the EPA's priority research goals include investigating ultrafine exposures and the role of different PM size fractions in health outcomes; exploring the potential for alternatives to the current PM mass-based standards; and examining the exposure and health effects of ultrafine components.

In California, the California Air Resources Board (CARB) has authority to set its own standards through an exemption granted under the Clean Air Act if granted by EPA. Recently, CARB has indicated that regulatory actions may be forthcoming to reduce mass and particle number from engines under the LEV III standards. Specifically, they have proposed an optional PM emission standard beginning in 2014 for super ultra low emission light-duty gasoline vehicles (SULEV) to have a solid particle number less than 6×10^{12} particles per mile, approximately equivalent to the European Union (EU) standard. This would allow vehicles to be certified for the EU standard and sold in CA without certification to the CARB PM emission standard. However, CARB has received feedback on several issues regarding testing procedures for this optional standard and may not include in its final recommendation to the state board due in December 2011. They anticipate now to continue pursuing a particle based standard once they have addressed concerns over testing procedures for the standard. At this time there are no plans for regulating heavy-duty diesel engines as diesel particulate filters appear to be the only lowest achievable technology for reducing DPM emissions and this is the current technology being used in all new diesel engines. CARB will continue to look at issues on how to measure emissions of semi-volatile and volatile ultrafine particles. Technical staff from CARB will publish their final recommendations for California's LEV-III standards to the Air Resources Board in late October 2011.

Local agencies, such as SCAQMD, can also take steps to mitigate ultrafine particle pollution. These can be mainly through mandating requirements on the transportation fleet and also the design of the transportation infrastructure itself. As discussed earlier, heavy-duty engines emit a higher number of particles in high acceleration and low-speed scenarios. Therefore, measures to alleviate congestion and thus promote free-flow of traffic may lead to a reduction in ambient ultrafine particles.

Recently, SCAQMD has announced plans for a new focus under their Multiple Air Toxic Exposure Study (MATES) program – MATES-IV. This study will include looking at measuring ultrafine particles as well as diesel PM near freeways, arterials, intersections, warehouse areas, rail lines, rail yards, and airports. The MATES-IV will examine ultrafine particles from both mobile platforms and fixed locations. Work plan and protocol development began this summer with advisory group meetings starting this fall and board approval by the end of the year. Monitoring for MATES-IV is planned to start in June 2012 and will continue for 1 year. It will be decided in the planning process if and how SCAQMD would conduct modeling of ultrafine particles.

At least one study, Hussein et al (2007), has attempted to model the near-roadway ultrafine particle number. The modeling exercised in the study used both a dispersion model to simulate the transport and turbulent mixing from the roadway to downwind locations and an aerosol dynamic model to simulate particle number size distribution. Two winter periods were simulated in Helsinki, Finland. Even though the model used a very low mixing volume, the model underpredicted concentrations 65 meters downwind by about a factor of 3. This underprediciton was attributed to uncertainty in the emission factors for the ultrafines and the lack of specificity of those emissions factors under varying ambient conditions (e.g., temperature and relative humidity).

In addition to modeling of ultrafine particles, recent efforts have focused on the development of emission inventories for ultrafine particles (Keogh and Sonntag 2011). In this study, the authors developed what they believe is the first published emission inventory of ultrafine particles generated by on-road mobile sources. This emissions inventory was prepared for urban Southeast-Queensland, covering 46,000 square kilometers, which includes all of the Brisbane metropolitan area. The inventory quantified both ultrafine particles (particle number) and particle mass emissions for the motor vehicle fleet, which included light and heavy duty vehicles and buses. The inventory covers a full size range of particles emitted by motor vehicles, and quantified emission rates for different vehicle types and road links. Average particle number and particle mass emission factors were derived using statistical analysis of more than 600 emission factors as identified in the published literature and combined with travel demand model data for the study region relating to 22,985 model links representing roads in the study region. The average particle number was considered suitable for use in other developed countries for quantifying particle inventories. This assumption is based on the finding in the statistical analysis that relatively few statistically significant differences were found between the mean values of published emission factors for different particle metrics for different countries of study and study location (measured on a dynamometer, in a tunnel, or in the vicinity of a road). Results from the study showed that for Brisbane, the annual emissions from on-road mobile sources was in aggregate about the same as annual particle number emissions due to artifact operations from Brisbane International Airport. The ultrafine inventory also revealed that while heavy-duty diesel vehicles only contributed 6% of the vehicle miles traveled, they accounted for more than half of the region's ultrafine particles.

6. Summary

Following are some major conclusions based on the current understanding of ultrafine particles.

- Studies have shown that ultrafine particles are at significantly elevated levels in near-roadway environments. These particles, which constitute most of the particle count in the ambient PM, have been linked to adverse health effects.
- Meteorological conditions have a significant effect on the distribution of ultrafine particles from roadways; the highest exposure to populations in the prevailing downwind direction.
- Although there have been major advances in the development of instrumentation to characterize ambient ultrafine particles, especially their number concentration, some challenges still remain. These mainly include the lack of standardized protocols which are essential for monitoring and developing regulations on ultrafine particles.
- Heavy-duty diesel trucks are the largest emitters of ultrafine particles among all vehicle classes. However, currently there are large uncertainties in relation to vehicle emission factors of ultrafine particles. This is partly due to the variability of emissions based on the fuel-type, fuel composition, and engine load and control technologies/after treatment devices.
- Measurement studies have shown that ultrafine particles are at significantly elevated levels in the vicinity of I-710. These high concentrations drop exponentially with the distance from the freeway and reach urban background levels at around 300 meters.
- Studies have shown that ultrafine particles can penetrate efficiently into indoor environments. Therefore, people living and working in the vicinity of major highways are exposed to high levels of ultrafine particles. Furthermore, in-vehicle exposure while driving on highways is also shown to be significant.
- Currently there are no immediate plans to directly regulate ambient levels. However, CARB has proposed a solid particle number standard for tailpipe emissions for SULEVs starting in 2014.

ABSTRACT

Emission control technologies designed to meet the 2007 and 2010 emission standards for heavy-duty diesel vehicles (HDDV) remove effectively the non-volatile fraction of particles, but are comparatively less efficient at controlling the semi-volatile components. A collaborative study between the California Air Resources Board (CARB) and the University of Southern California was initiated to investigate the physicochemical and toxicological characteristics of the semi-volatile and non-volatile particulate matter (PM) fractions from HDDV emissions. This paper reports the physical properties, including size distribution, volatility (in terms of number and mass), surface diameter, and agglomeration of particles emitted from HDDV retrofitted with advanced emission control devices. Four vehicles in combination with six after-treatment devices (V-SCRT®, Z-SCRT®, CRT®, DPX, Hybrid-CCRT®, EPF) were tested under three driving cycles: steady state (cruise), transient (urban dynamometer driving schedule, UDDS), and idle. An HDDV without any control device is served as the baseline vehicle.

Substantial reduction of PM mass emissions (>90%) was accomplished for the HDDV operating with advanced emission control technologies. This reduction was not observed for particle number concentrations under cruise conditions, with the exceptions of the Hybrid-CCRT® and EPF vehicles, which were efficient in controlling both—mass and number emissions. In general, significant nucleation mode particles (<50 nm) were formed during cruise cycles in comparison with the UDDS cycles, which emit higher PM mass in the accumulation mode. The nucleation mode particles (<50 nm) were mainly internally mixed, and evaporated considerably between 150 and 230 °C. Compared to the baseline vehicle, particles from vehicles with controls (except of the Hybrid-CCRT®) had a higher mass specific surface area.

1. Introduction

Recent *in vitro* and *in vivo* animal studies suggest that ultrafine particles (for this study particles <180 nm) may be more toxic than both $PM_{2.5}$ and PM_{10} (Li et al., 2003; Oberdorster, 2000). The most prominent sources of ultrafine particles in an urban metropolis like Los Angeles are vehicular emissions and secondary photochemical reactions (Fine et al., 2004; Zhang et al., 2004). Heavy-duty diesel trucks constitute only a small fraction of the total fleet in California but have an important contribution to the emissions of fine and ultrafine particles. Diesel

exhaust particles (DEP) are normally agglomerates of hundreds of volatile/semi-volatile species adsorbed onto its refractory carbonaceous core (Bayona et al., 1988). Some of these constituents are known carcinogens (Stayner et al., 1998; Solomon and Balmes, 2003). Also DEP are capable of inducing systemic inflammation by imparting oxidative stress in susceptible cells (Koike et al., 2002; Shima et al., 2006) and are instrumental in causing asthma symptoms and may contribute to cardiopulmonary diseases (McClellan, 1987; Dockery et al., 1993, Nel et al., 2001).

As general perception has emerged towards the potential risks of diesel particulate matter (PM), policy makers are promulgating stricter emission control rules and regulations. The US EPA 2007 emissions standard reduces the diesel PM mass emission from heavy-duty engines ten fold from the old 0.1 g $bhp^{-1} h^{-1}$ PM limit to 0.01 g $bhp^{-1} h^{-1}$ (Merrion, 2003). To effectively meet such stringent emission standards, various advanced engine design and control technologies are being considered and rigorously evaluated for the newer fleet of heavy-duty trucks. While these after-treatment devices (such as diesel particulate filters (DPF)) have been highly efficient in removing refractory solid particles (>50 nm), some of the potentially harmful volatile and semi-volatile species (such as PAHs), originally emitted in the vapor phase at high plume temperature, may penetrate through (Kittelson et al., 2006; Matter et al., 1999a). As the exhaust temperature decreases drastically at the tail pipe exit, these vapor phase species condense and form fresh nucleation mode particles. (Kittelson, 1998).

Various on-road as well as dynamometer experiments have shown that these particles are predominantly externally mixed (except particles <20 nm). The volatile fraction roughly contributes 10–30% of the total mass and 70–90% of particles by number (Sakurai et al., 2003). Particle volatility is strongly dependent on gas to particle phase partitioning and is extremely sensitive to dilution and temperature conditions (Liu et al., 2007a; Abdul-Khalek et al., 1999; Wei et al., 2001a, b; Kuhn et al., 2005, Biswas et al., 2007). Zhang and Wexler (2004) showed that condensation, evaporation and dilution are the three major factors affecting the evolution of size distribution near a freeway. Thus, particle volatility plays key roles in shaping the particle size spectrum and eventually determining the level of human exposure to different aerosol components (volatile or non-volatile) originating form traffic emissions.

In addition to volatility, particle surface characteristics are important physical parameters in determining PM toxicity. Some researchers have argued that particle surface area is a better metric to predict health endpoints than particle mass or number and should be included as an essential element while considering new regulatory tools (Maynard, 2006; Oberdörster et al., 2005; Nygaard et al., 2004). This is because the availability of reaction sites to cause cell damage is more likely to be directly proportional to surface area available to lungs (Maynard, 2006). Surface properties will also be relevant in future as the control technologies are reported to generate considerable number of small particles (Bagley et al., 1998; Geller et al., 2005) leading to a net increase in surface area per unit mass of PM.

The primary objective of this collaborative study between the California Air Resources Board (CARB) and the University of Southern California is to estimate physicochemical and toxicological characteristics of the volatile and non-volatile fractions of particles emitted from a variety of different engines, fuels and emissions control, each operating under different driving conditions using a dynamometer setup. In this paper, we will focus only on the physical PM properties, i.e. size distribution, volatility and surface characteristics for diesel vehicles retrofitted with state-of-the-art after-treatment devices. Comparisons within HD vehicle types and driving cycles and also with respect to a baseline vehicle (without any control technology) will be discussed. Details of PM chemical and toxicological characteristics from these vehicles will follow in subsequent publications.

2. Methods

Experiments were carried out at the CARB's heavy-duty diesel emission testing laboratory (HDETL) in downtown Los Angeles. Ayala et al. (2002) described the dynamometer specifications in details. Fig. 1 shows the schematic of the experimental setup. The sampling train includes heavy-duty chassis dynamometer, constant volume sampling (CVS) dilution tunnel and aerosol samplers. Diesel vehicle exhausts were transported by a stainless steel hosepipe and diluted with filtered air through the CVS. Measurements were taken 18 diameter lengths downstream of the exhaust introduction in the CVS. Three driving cycles, i.e. steady state cruise (50 mph), transient (EPA urban dynamometer driving schedule (UDDS)) and idle were tested to simulate various real-world driving conditions. The fuel used to run the engines was CARB ultra-low sulfur diesel (ULSD) with sulfur content <15 ppm. Tunnel blank levels were measured and vehicles were conditioned (warmed up) everyday before the start of official runs. The CVS was cleaned before starting the project.

2.1. Vehicles

The test fleet comprised of four heavy-duty diesel vehicles (HDDV) in seven configurations (Table 1). A 1998 Kenworth truck was served as a baseline vehicle, without any emission control technology. The same Kenworth truck was also tested with three different control technologies: a continuously regenerating technology (CRT®), consisting of a diesel oxidation catalyst (DOC) followed by an uncatalyzed trap; CRT® in combination with a selective catalytic reduction system (Zeolite- or vanadium-based SCRT®s). The SCRT systems used for this study were prototype systems and not yet ready for full-scale production. The other three test vehicles were a diesel hybrid electric bus, a school bus, and a Caltrans truck.

The two SCRT® technologies consist of a wall-flow particulate trap (CRT) followed by an SCR section. The

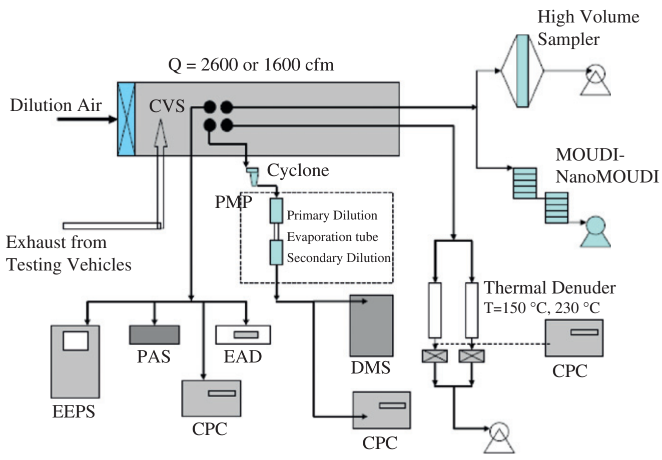

Fig. 1. Experimental setup.

CRT® was the same in each configuration. The difference between them lies in the choice of catalysts (vanadium or Zeolite) for the SCR to control oxides of nitrogen (NO_x). The Caltrans truck, with a smaller engine (7.6 L) than the Kenworth truck (11 L, Table 1), is retrofitted with an Engelhard DPX® filter. The DPX® filter is comprised of a diesel particulate trap with a catalytic wash-coat. The diesel hybrid electric bus (San Joaquin Valley RTD) is equipped with a catalyzed continuously regenerative trap, or CCRT®, consisting of a DOC followed by a catalyzed trap, which was virtually brand-new, with only 1000 miles on the odometer. The last test vehicle was an Elk Grove school bus, equipped with an electric particle filter (EPF). The EPF consists of a non-catalyzed silicon carbide substrate for PM control, coupled with an electric heating element and a small blower. The trap is regenerated periodically using electricity from the grid (plug in configuration) during non-operational periods—mostly at night. Hereafter, the test fleet is referred as baseline, CRT®, V-SCRT®, Z-SCRT®, DPX®, Hybrid-CCRT® and EPF.

The dilution air flow rate at CVS was 2600 cfm ($74\,m^3\,min^{-1}$) for cruise and UDDS cycles, and 1600 cfm ($45.4\,m^3\,min^{-1}$) for the idle. For EPF and Hybrid-CCRT®, the flow rates were maintained at 1600 cfm for all cycles. These flow rates result in approximate dilution ratios of 6–9 for cruise, 5–80 for UDDS, and 15–25 for idle.

2.2. Equipment and instruments

Specific descriptions of some of the instruments and equipment used for this study are provided in this section.

2.2.1. Nano-MOUDI

Size-resolved samples were collected using a micro-orifice uniform deposited impactor (MOUDI) upstream of a nano-MOUDI (MSP Corporation, Minneapolis, MN, USA) loaded with pre-cleaned aluminum foil substrates. Particles were classified in the following aerodynamic size ranges: 10–18 nm, 18–32 nm, 32–56 nm, 56–100 nm, 100–180 nm, 180 nm–2.5 μm, and >2.5 μm. The MOUDI-Nano MOUDI tandem was operated for multiple runs in order to accumulate sufficient mass for chemical analysis for each vehicle and driving cycle.

2.2.2. DMS/EEPS

Size distribution of engine exhausts from the CVS was monitored every second by two multiple channel differential mobility spectrometers: a DMS500 (Cambustion) and an engine exhaust particle sizer (EEPS 3090, TSI Inc.). Both DMS and EEPS classify particles on the basis of their mobility diameter. The cut-off size ranges of EEPS and DMS are 5.6–523 nm and 4.5–1000 nm, respectively. With high-time resolutions, they are both capable of tracking transient particle behavior, especially during UDDS cycles. With few exceptions (V-SCRT, Z-SCRT only), in which the DMS was placed downstream of the particle measurement program (PMP) sampler, both instruments were connected directly to CVS.

2.2.3. PMP

A PMP protocol was developed in Europe to measure the solid particle emissions from light-duty vehicles. The sampling train of PMP contains a volatile particle remover (VPR) and a particle counter. The VPR provides two stage dilution connected by an evaporation tube (ET). The temperature for the primary dilution, ET and secondary dilution is 150, 300, and ~35 °C, respectively. Detailed information for the PMP can be seen in Herner et al. (2007a).

2.2.4. Thermodenuder

Particle volatility was determined by two thermodenuders (Model ELA-230, Dekati Ltd.) sampling in parallel, each heating the entering aerosol to 150 and 230 °C, respectively. The thermodenuder consists of a heating section, followed by an adsorption/cooling unit. As aerosol stream was drawn from the CVS and passed through the heating tube, part of its volatile/semi-volatile components was sheared off. These labile species adsorb onto a layer of activated charcoal placed on the walls of the thermodenuder, leaving the non-volatile PM fraction to be collected on Teflon filters (47 mm, PTFE, Gelman) placed downstream of the thermodenuders. Multiple runs were

integrated to achieve desired sample mass loadings on these filters to perform various chemical and toxicological analyses. Solid particle number concentrations and size distributions were monitored intermittently by a condensation particle counter (CPC 3022 A, TSI Inc., MN) and a differential mobility particle sizer (DMA, TSI 3085).

2.2.5. Electrical aerosol detector (EAD)

Several instruments are currently in use to assess PM surface related properties. In this study, a diffusion charger, the TSI EAD 3070A, was used to characterize the transient as well as steady state behavior of aerosols. The EAD consists of a unipolar diffusion charger and an electrometer. Particles are charged by diffusion and then drawn through the electrometer which records total current (I) carried by the aerosol stream. Studies have shown that the response of EAD is a function of $D_p^{1.13-1.16}$ (Woo et al., 2001; Jung and Kittelson, 2005; Wilson et al., 2007). This response is particularly an useful PM metric because it corresponds to the actual particle surface area exposed to the environment and can be used to quantify, for example, the area available for adsorption of gaseous species or for interaction with the epithelial tissue in the lungs (Wilson et al., 2007). Because the EAD signal is closely related to aerosol diameter (Jung and Kittelson, 2005) the manufacturer has marketed this instrument to indicate total aerosol length in mm cm^{-3}.

2.3. Data reduction

The physical properties of aerosols from the various vehicles and driving cycles were reduced to three variables, originally introduced by Ntziachristos and Samaras (2006) intended to serve as means to discriminate the effects of fuel, driving condition and vehicle control technology on particle emissions in dynamometer studies. These variables are as follows:

- *Reduced variable 1*: volatility ratio

$$R = \frac{N_{\mathrm{Exhaust}}}{N_{\mathrm{TD}}}, \tag{1}$$

where N_{Exhaust} is the total dilution corrected DMS or EEPS number concentration at the CVS ($D_p \geqslant 7$ nm), N_{TD} the number concentration measured by CPC after the thermodenuders ($D_p \geqslant 7$ nm).
This is a measure of particle volatility in terms of number concentration.

- *Reduced variable 2*: surface-rated diameter
The EAD electrometer current is given by (Woo et al., 2001)

$$I = N_p N_t e Q, \tag{2}$$

where I is the total current measured by EAD (fA); N_p the charge (charge particle^{-1}) attachment, $0.0181 D_s^{1.13}$ (Jung and Kittelson, 2005); D_s the surface-rated diameter (nm); e the elementary charge, 1.6×10^{-19} C; Q the aerosol flow rate through EAD, 1.5 lpm (1.5 lpm aerosol, 1 lpm sheath flow); N_t the total exhaust particle number, 10–1000 nm from DMS, 10–523 nm for EEPS.
Note: particle number in the 523–1000 nm range is insignificant.
Now substituting in Eq. (2)

$$D_s = \left(\frac{I}{0.0181 N_t e Q}\right)^{1/1.13}. \tag{3}$$

- *Reduced variable 3*: mass specific surface area

$$A = \frac{S}{\mathrm{PM}}, \tag{4}$$

where A is the mass specific surface area (m^2 g^{-1}), S the surface concentration, m^2 km^{-1}. For the calculation of A, the EAD current was converted to particle surface area using the conversion factor of 65 μm^2 pA^{-1} ($R^2 = 0.9$, alveolar deposition) reported by Wilson et al. (2007). PM is the total particle mass collected between 10 nm and 2.5 μm nano-MOUDI stages, mg km^{-1}.
The nano-MOUDI substrate mass ($\leqslant$2.5 μm) measurements were in excellent agreement with parallel CARB reference filter measurements ($R^2 = 0.99$; slope = 0.95, intercept = 2.4 mg km^{-1}) and used to calculate mass-based parameters. Filter mass was used only for V-SCRT-Cruise (nano-Moudi data not available).
It is a measure of particle agglomeration. Particle agglomeration increases with decreasing A.

3. Results and discussion

3.1. Size distribution

Fig. 2 presents tunnel blank-subtracted mean size distributions for vehicles at different operating conditions. These distributions derived from DMS/EEPS measurements are grand averages of multiple runs for each driving cycle. The data are reported in terms of number per vehicle kilometer traveled for cruise and UDDS cycles, and number per hour for idle. The primary focus here is to give a brief overview in order to provide meaningful insights and support to some of the findings described in subsequent sections.

While performing preliminary quality assurance–quality control (QA/QC) of real time data for SCRT®s (V-Cruise, UDDS, Z-Cruise), we noticed that few EEPS sizes channels (10–20 nm) were almost always saturated due to particle over-loadings. These size bins were subsequently replaced with corresponding secondary dilution-corrected DMS data (the DMS was placed downstream of the PMP secondary dilution with the ET off) to obtain more accurate size distributions. For rest of the test fleet (except CRT®), we used data from the DMS, which was directly connected to the CVS. We have added a tunnel blank distribution in Fig. 2f (baseline vehicle).

Size distribution patterns for both SCRT®s are quite similar with sharp modes (Fig. 2a, b) at ~10 nm. The distinguishable feature is the less prominent nucleation mode for UDDS runs especially for the Z-SCRT-UDDS cycle. This may be due to the fact that the Zeolite-SCRT requires

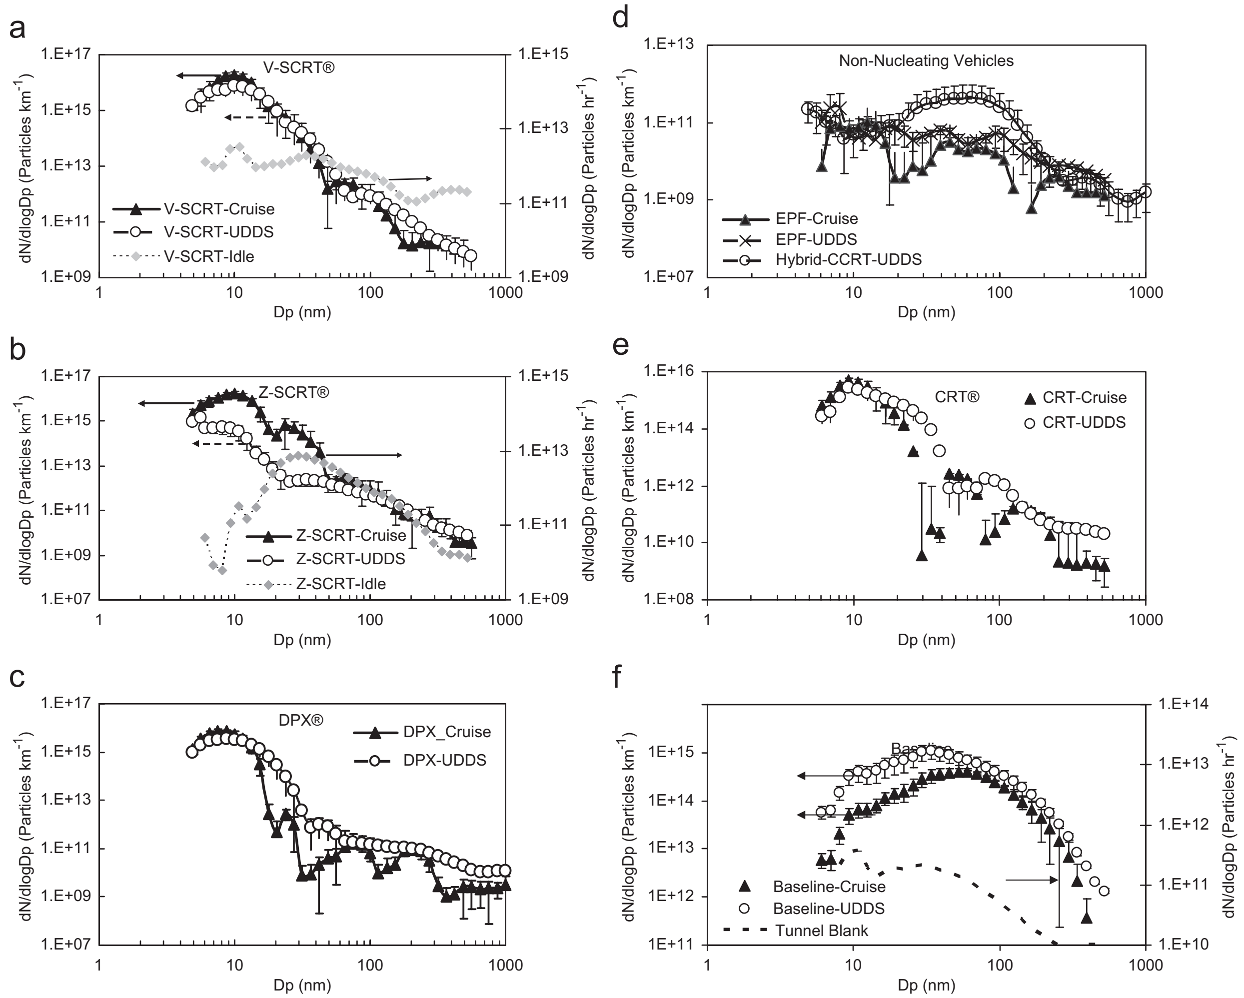

Fig. 2. Particle number size distribution.

much higher temperature to trigger and sustain nucleation than the vanadium-based SCRT catalysts (Herner et al., 2007b). Moreover, in general the zeolite catalysts have lot more catalytic surface area than vanadium catalysts and the Z-SCRT system used for this study is completely new (Table 1). These provide higher storage sites for sulfate generated by the upstream DOC and DPF during transient and low-temperature testing.

Although the main purpose of SCR® technologies is to reduce NO_x by ammonia, at elevated temperatures, their in-built catalysts may encourage the formation of sulfate, an important component acting potentially as seed aerosol for particle formation by condensation of semi-volatile organic vapors, as explained earlier. Chemical data collected will be used to determine composition and will be reported in future publications. For a brief sampling period, we bypassed the SCR portion from exhaust after-treatment system (SCRT®) just to investigate the impact of the SCR catalysts. Although, this modification did not result in visible alteration of the shape (on log scale) of the distributions (CRT®, Fig. 2e), number concentration decreased by a factor of 2–3 from the V-SCRT and Z-SCRT cruise cycles—suggesting SCR catalyst's role on nucleation. Unlike cruise or UDDS cycles, idle runs are characterized with remarkably low particulate number emission rates, coupled with broad size distributions (Fig. 2a, b). The second test engine, Engelherd-DPX® (Fig. 2c) displays a dominant nucleation mode, almost identically to the SCRTs/CRT. It has been hypothesized that the catalyst wash-coat on DPF (if saturated) may be enhancing the conversion of SO_2 to SO_3/sulfate and partially stimulates the nucleation process (Hansen et al., 2001).

Contrary to the general notion that particulate filters augment nucleation, the hybrid vehicles (with a CCRT®) and the school bus (with an EPF) were found to be highly efficient in suppressing if not eliminating this PM mode. The Hybrid-CCRT® vehicle (Fig. 2d) resulted in concentrations (CVS) in the range of $\sim 10^4$ particles cm^{-3}, thus a 1000-fold improvement over the previously tested vehicles ($>10^7$ particles cm^{-3}). We hypothesize that the initial capacity of its relatively new trap (with only 1000 miles on it) to store sulfur has significantly suppressed the formation of nuclei mode particles. Once all the storage sites are saturated, nucleated sulfate particles are expected (Kittelson et al., 2006). For this vehicle, only a few odd large particles are left downstream (Fig. 2d). The school bus (Fig. 2d), however, was the cleanest amongst the entire test fleet with number emissions <1500 particles cm^{-3} measured in the CVS. It is important to note here that this vehicle is equipped only with an uncatalyzed filter (EPF), which is least likely to enhance the nucleation process. Thus, nucleation is not only control device specific but also a function of age and operating conditions, e.g. temperature of the catalysts.

The baseline truck, on the other hand, represents the older genre of vehicles and was found to emit substantial amounts of larger particles (Fig. 2f) with modes in the 60–100 nm range. Because of their large surface area, these accumulation mode particles act as adsorption sites and thus perfect sinks for organic vapors, leading to suppression of nucleation mode (Liu et al., 2007b).

3.2. *Size segregated mass emission factors*

Size fractionated mass emissions factors (in $mg\,km^{-1}$ or $mg\,h^{-1}$) are calculated based on the loadings on the MOUDI-nano-MOUDI impaction plates. The mass loadings on the individual substrates are generally low for retrofitted vehicles and depending on size ranges variation in the order of 20–40% (standard deviation/mean; from few duplicate measurements) are observed.

Although a direct correspondence of mobility and aerodynamic diameters is not accurate without establishing some conversion factors, we can utilize the information from Table 2 to complement the mobility size distributions (Fig. 2) described before. Number and mass-based size distributions are found to be in reasonable agreement with each other in terms of their trends.

The emission factors are remarkably low (~1–12 mg km^{-1}) for the fleet operated with control technologies compared to the baseline vehicle (~80–316 $mg\,km^{-1}$). While the majority ($>95\%$) of PM mass is concentrated between 100 nm and 2.5 μm for the baseline truck, nuclei modes are clearly visible for vehicles retrofitted with control devices. Significant reduction ($>90\%$) of the mass is achieved for vehicles retrofitted with control devices.

Some general trends and inferences can be drawn from Fig. 2 and Table 2. Consistent with previous studies (Kittelson et al., 2006; Vaaraslahti et al., 2004) the majority of the control technologies evaluated here have promoted bulk production of nano-size (nucleation) particles during steady state and high-speed segment of transient running cycles. The cruise cycles on average generate higher nucleation and lesser accumulation mode particles than the UDDS cycles. The differences between these driving cycles are even more pronounced in mass distributions (Table 2): significant shifts towards larger sizes are apparent in UDDS runs due to increased emission of accumulation mode particles during the acceleration processes (Polidori et al., 2008). Aerosol formation mechanism, poorly understood till date, seems to be a function of vehicle type and driving conditions and retrofit design.

Fig. 3 is an informative graph showing a plot of number EFs vs. mass EFs (nano-MOUDI, except V-SCRT-Cruise) for each vehicle and driving cycle. Each data point corresponds to a cruise or an UDDS cycle for a given vehicle. The graph shows that for several of the after-treatment devices tested, particle number emissions increase with reduced mass emissions. There are some outliers or exceptions observed for Z-SCRT at UDDS cycle, Hybrid-CCRT®, EPF and Idle (not shown) for which both number and mass EFs are relatively low. Thus, most of the new after-treatment devices appear to be highly efficient in reducing mass emissions but some are not effective in controlling number concentrations due to the formation of nuclei mode particles. These findings are potentially very important if number-based standards are considered in the future.

3.3. *Particle volatility*

The extent of particle volatility in terms of total count is illustrated quantitatively by the reduced variable 1 (R) plotted in Fig. 4 for various vehicles and cycles. R was calculated at 150 and 230 °C except in few occasions (Hybrid-CCRT®, EPF) when both the thermodenuders were operated at 150 °C to maximize our capability to collect mass of non-volatile particles. Theoretically, this ratio (R) should be greater or equal to unity and its increase corresponds to higher particle volatility. For the majority of the cases, R at 230 °C is at least an order of magnitude higher than their counterparts at 150 °C, indicating complete disappearance of large fraction of particles within this temperature window.

Particle volatility was also observed to be somewhat sensitive to driving conditions and type of control technology used. For instance, cruise mode particles are

Table 2
Size-fractionated mass EFs ($mg\,km^{-1}$ for cruise and UDDS, $mg\,h^{-1}$ for idle)

Size (nm)	V-SCRT		Z-SCRT			DPX			Hybrid-CCRT	CRT		EPF			Baseline

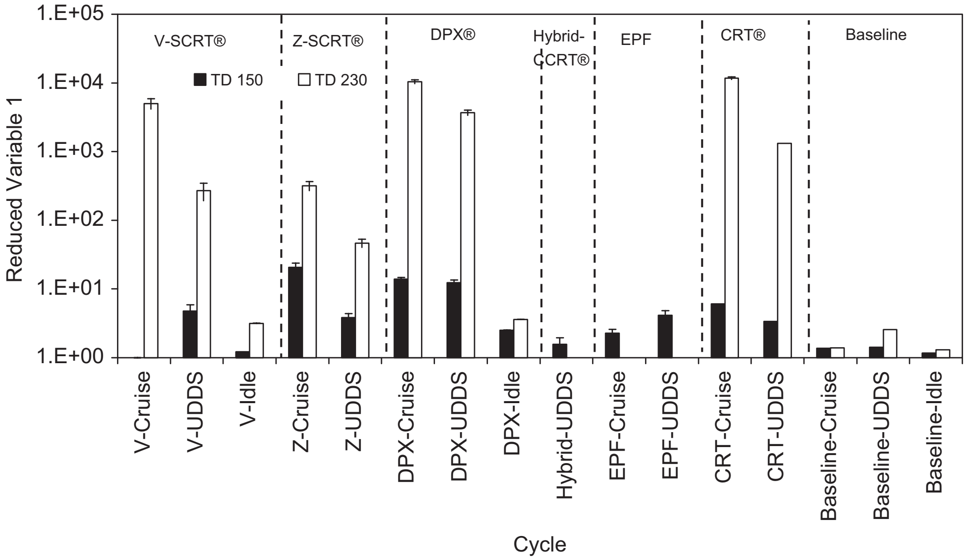

Fig. 4. Reduced variable 1 (*R*): ratio of total particle to solid or thermodenuded particle count.

extremely volatile with maximum *R*-values (~4000–10,000) at 230 °C for V-SCRT®, DPX® and CRT®. The fact that <~0.1% of particles persisted at 230 °C for most of the fleet with control technologies can logically be explained by the presence of unstable (volatile) fresh nano particles. Although the same Kenworth truck is used to evaluate various after-treatment devices (V-SCRT®, Z-SCRT®, CRT®), the Zeolite catalysts, especially during UDDS runs, seem to emit particles with a slightly higher heat resilience, which is consistent with the fact that nucleation mode particle were in lower concentrations for that vehicle and cycle (Fig. 2b). As expected, the baseline vehicle had the highest fraction of non-volatile particles in all cycles. Lower volatility is also observed during all idle runs, EPF and Hybrid-CCRT® vehicles. While we expect the baseline truck to emit large amounts of refractory elemental carbon, lower number loss for other vehicles/cycles should be attributed to their insignificant particle emission rate and/or absence of the nucleation mode particle formation.

The significant particle number loss between 150 and 230 °C, especially for cruise cycles, may be better elucidated by the evaporation profiles shown in Fig. 5. The majority of particles in the 7–20 nm size range for DPX® and CRT® have disappeared as the aerosol stream is heated from 150 to 230 °C. This is in total contrast to the baseline vehicle, where no noticeable shift in size spectrum is observed. Matter et al. (1999a, b) reported very similar thermal desorption trends between 172 and 204 °C for particles sampled downstream of a DPF. These results further justify our temperature choices for the two thermodenuders, which will hopefully enable us to discern differences in

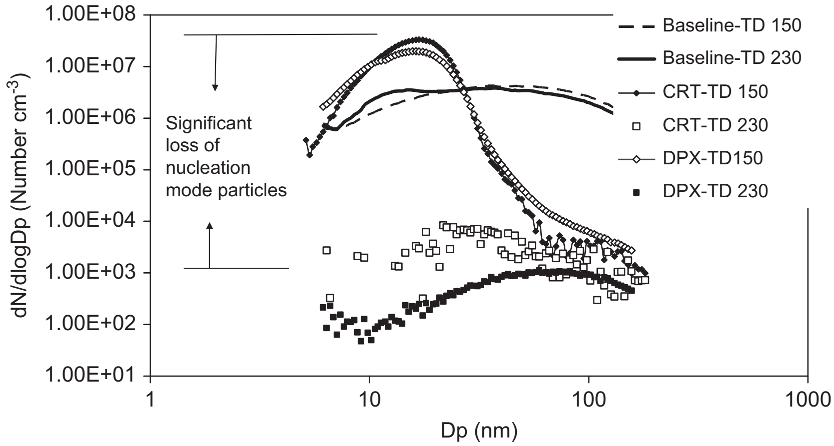

Fig. 5. Size distribution of thermodenuded aerosols for cruise mode.

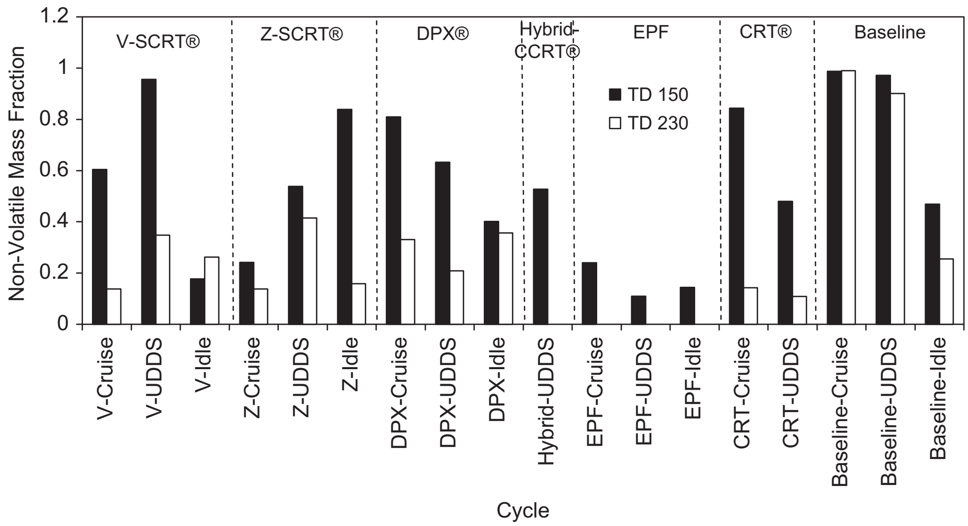

Fig. 6. Non-volatile mass fraction at different thermodenuder temperature settings.

the toxicological responses associated with the nucleation mode on particles of these different vehicles.

Fig. 6 presents the amount of mass fraction retained (non-volatiles) at 150 and 230 °C. We obtained these ratios from gravimetric filter measurement of denuded and undenuded samples. Particle number is not a good surrogate of its mass. Thus, except in the case of baseline vehicle, number loss (Figs. 4 and 5) has not linearly translated into equivalent particle mass reduction. While >99% of the particles completely disappear at 230 °C for SCRTs, CRT and DPX at cruise and UDDS runs, an appreciable fraction of mass (20–40%) remains intact. Quite a reverse trend is observed for idling, EPF and Hybrid-CCRT® (low-number emission scenarios with insignificant nucleation mode)—relatively low number volatility is accompanied with significant mass loss. A study (Biswas et al., 2007) conducted in close proximity of a freeway with the highest percentage of diesel fleet (~18%) in the USA demonstrated that a substantial amount of particle mass could be lost from larger ultrafine particles (>40 nm) due to heating without loosing a significant amount of their total counts. The mode of the size distribution shifted to lower size ranges, as a result of the depletion of the aerosol mass, but overall these particles simply decreased in size but did not disappear during heating, unlike the much smaller nucleation mode PM.

Particle volatility analysis could be used to at least in part infer particle chemical composition. Researchers have shown that diesel nuclei mode particles are dynamic mixtures of sulfate and organics (Grose et al., 2006; Scheer et al., 2005). Sulfates can either be in the form of pure sulfuric acid (classical binary nucleation theory of H_2SO_4–H_2O) or neutralized salts (NH_4SO_4, NH_4HSO_4, etc.). The neutralized species are refractory even at 200 °C; however, H_2SO_4 evaporates completely at a much lower temperature (~125–150 °C) due to its high vapor pressure (Orsini et al., 1999; Schmidt et al., 2002). The organic

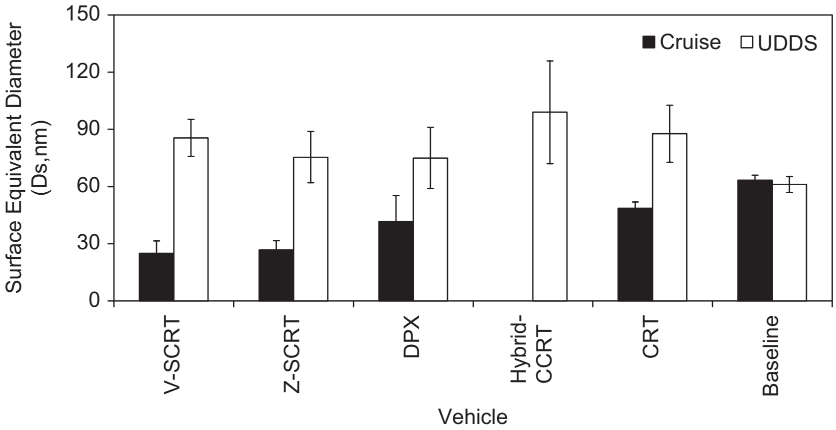

Fig. 7. Reduced variable 2: surface-rated diameter.

fraction is comprised not only of volatile unburned lube oil constituents, but also residual low vapor pressure organics (Tobias et al., 2001). From TEM analysis of particles captured downstream of a DPF, Mathis et al. (2004) further inferred that these nano-particles are likely to be composites of various species possessing diverse volatility characteristics. Although, from the above discussion, the bulk loss of nucleation mode particles in Figs. 4 and 5 appears to be due to evaporation of sulfates and volatile/semi-volatile organics between 150 and 230 °C, complete chemical speciation is essential to reach any educated conclusion and will be the topic of a subsequent publication of our group.

3.4. Particle surface properties

3.4.1. Reduced variable 2: surface-rated diameter

The surface-rated diameters (D_s) calculated from EAD surface concentrations are illustrated in Fig. 8. Ideally, D_s should be very close, if not higher than the arithmetic mean particle diameter. Average surface-rated diameters are calculated for all the vehicles except for school bus (EPF) where EAD signals are below the instruments detection limit. It is evident from the plot that cruise mode D_s, irrespective of types of control technologies, are smaller (~25–40 nm) compared to the transient driving cycles (~75–100 nm). This is consistent with the increased formation of elevated level of nuclei mode particles ($<$50 nm) during the steady state and larger amount of accumulation mode particles in UDDS cycles. Considering negligible variations in the accumulation modes (Harris and Maricq, 2001), also shown in Fig. 2 and Table 2, we can thus use D_s as a good indicator for the presence or absence of freshly nucleated particles.

During a typical transient run (i.e. UDDS cycles), an engine experiences acceleration, deceleration, steady state, and idling phases, which result in frequent changes in exhaust particle characteristics in terms of their size distribution, total count and surface concentration. Acceleration and high-speed cruise modes produce significant number of small particles, followed by their absence during deceleration and idling. Thus, rapid variation in D_s coupled with higher accumulation modes (Fig. 2, Table 2) eventually translates into higher mean surface diameter for UDDS runs. This phenomenon can be elucidated succinctly by time series plots (Fig. 8a, b) of particle number, EAD response (fA) and corresponding mean surface diameter (D_s) for a selected DPX® UDDS run (Fig. 8a). EAD signals and total counts track each other well; however, the D_s plot follows a reverse trend. Surface diameter goes up and down (50–500 nm) at the initiation of acceleration or deceleration when the total count is still low, or drops down drastically. The lowest surface diameter (~20–30 nm) was recorded during the later stages of acceleration, or at high-load conditions (steady state) as small particles predominate the size distribution.

Unlike the other vehicles (where similar behavior observed as that of Fig. 8a), the baseline truck maintains a high particle number concentration ($>10^6$ particle cm^{-3}) over the entire span of the UDDS runs, which greatly dampens the fluctuation in D_s (Fig. 8b). This explains its resultant lower mean surface diameter (~60 nm) (Fig. 7) despite the significant contribution of accumulation mode particles. Also, the lower difference in D_s for the cruise and UDDS can be attributed to the relatively higher number of nucleation mode particles in UDDS than cruise unlike other vehicles.

3.4.2. Reduced variable 3: mass specific surface concentration

Fig. 9 shows mass specific surface concentrations for the various vehicles and driving cycles tested. This PM property is inversely proportional to the mean particle size of DEPs, thereby providing an indirect measure of the extent of particle agglomeration. Therefore, the decrease of 'A' implies an increased contribution of coagulated or accumulation mode particles. The accumulation mode particles scavenge nucleation precursor species (Liu et al., 2007b), as mentioned before. Thus, particle agglomeration is an important parameter to indicate suppression of nuclei mode particles.

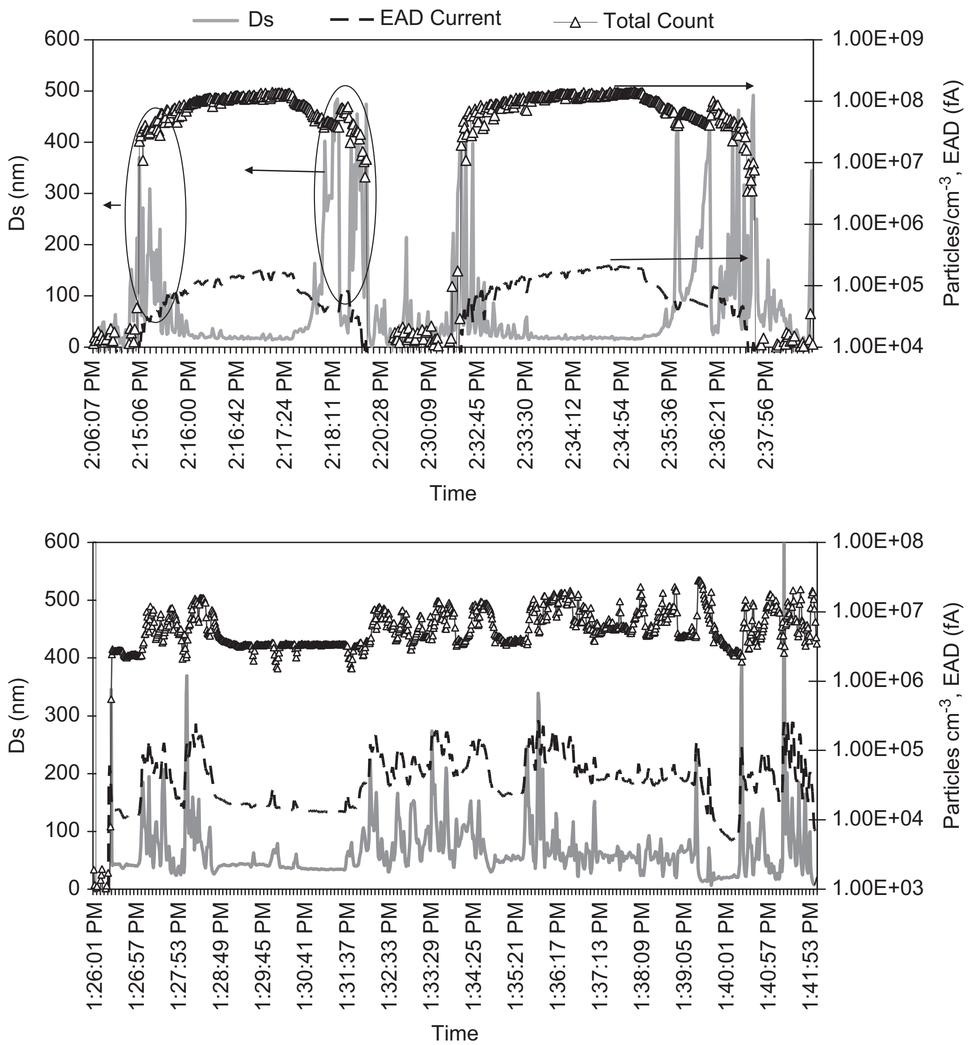

Fig. 8. Time series of surface diameter (D_s), surface concentration (EAD signal and total particle concentration (DMS count) for (a) Engleherd–DPX, (b) baseline–UDDS run.

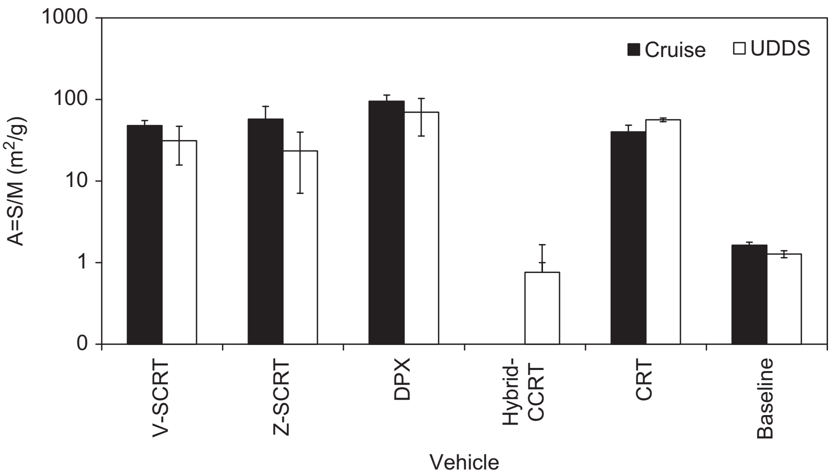

Fig. 9. Reduced variable 3: mass specific surface concentration.

The mass specific surface area, based on EAD surface concentration, have values in the range of 1–100 $m^2 g^{-1}$, which are consistent with those measured by Brunauer–-Emmett–Teller (BET) technique (26–72 $m^2 g^{-1}$, Duran et al., 2002). A study by Ntziachristos and Samaras (2006) reported somewhat higher values of the mass specific surface area from heavy-duty passenger vehicles (300–500 $m^2 g^{-1}$).

Cruise cycles on average have slightly higher values (5–10%) of '*A*' compared to their respective UDDS cycles of a given vehicle, indicating their less agglomerated particle structures. Although the shape and size of accumulation modes are quite similar, if not identical, for both cycles (Fig. 2), steady state operations are associated with higher nucleation mode. As EAD signal is weighed towards smaller particles (Jung and Kittelson, 2005), cruise cycles are likely to trigger more EAD response than transient cycles. On the other hand, accumulation modes prevail over nucleation modes (Fig. 2) for Hybrid-CCRT® at UDDS runs and the baseline vehicle, resulting in lower mass specific surface concentrations (~1 $m^2 g^{-1}$). Higher fractal agglomerates emitted by the baseline vehicle may result in a lower value of *A*. The effect of nucleation is also observed for Z-SCRT-UDDS runs, which exhibited slightly lower (though statistically insignificant) '*A*' compared to other SCRTs configurations.

4. Summary and conclusion

This investigation presents some of the first detailed particle characterization for advanced NO_x and PM retrofits for heavy-duty diesel vehicles. The test fleet includes a diesel hybrid electric with a DPF (Hybrid-CCRT®), a continuously regenerating technology (CRT®), a vanadium-based SCR catalyst with a CRT® (V-SCRT®), a Zeolite-based SCR catalyst with a CRT® (Z-SCRT®), a DPX, and an EPF. An HDDV vehicle without emission controls served as the baseline vehicle. The fleet was tested under three driving cycles: cruise at 50 mph. UDDS and idle.

Remarkable reductions in PM mass emissions (>90%) were found for the test fleet compared to the baseline vehicle. However, enhanced nucleation mode particles were observed for some of the vehicles especially during cruise cycles. Comparing to cruise cycles, the UDDS cycles emit higher particle mass in the accumulation mode. Idle runs are characterized with remarkably low particle number emission rates, coupled with fairly broad size distributions. The Hybrid-CCRT® and EPF vehicles were efficient in controlling both mass and number emissions.

The majority of particles by number evaporated by heating the aerosol to 150–230 °C, suggesting the nucleation mode particles are predominantly internally mixed and consist of semi-volatile compounds. Particles from the test fleet (except Hybrid-CCRT®) have shown about 100-fold higher active surface area per unit mass than the baseline vehicle. Chemical and toxicological analysis of the volatile and non-volatile fractions of PM emissions from the test fleet are under way and will be reported in future publications.

Acknowledgments

This research is sponsored by the California Air Resources Board (CARB), California Energy Commission (CEC), and South Coast Air Quality Management District (SCAQMD) through Grant no. 05-308 to USC. The authors would like to thank Dr. Harish Phuleria, Dr. Michael Geller, Ning Zhi, Payam Pakbin, Mohammad Arhami, Ralph Rodas, and George Gatt for their valuable support during experimental phase. This research has not been subjected to CARB's peer and policy review, and official endorsements should not be inferred.

FINAL 2006

San Pedro Bay Ports Clean Air Action Plan

OVERVIEW

THE PORT OF LOS ANGELES

THE PORT OF LONG BEACH

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY

California Environmental Protection Agency
Air Resources Board

AQMD

Prepared with the participation and cooperation of the staff of the US Environmental Protection Agency, California Air Resources Board and the South Coast Air Quality Management District.

STATEMENTS OF THE PRESIDENTS OF THE LOS ANGELES BOARD OF HARBOR COMMISSIONERS AND THE LONG BEACH BOARD OF HARBOR COMMISSIONERS

At the Joint Special Meetings of the Los Angeles Board of Harbor Commissioners and the Long Beach Board of Harbor Commissioners (the "Commissions") held on Monday, November 20, 2006, at 1:00 P.M. in the Long Beach City Council Chamber, 333 W. Ocean Blvd., Long Beach, California, the two Commissions unanimously adopted the San Pedro Bay Ports Clean Air Action Plan ("CAAP" or "Plan") as reflected in the minute record of the proceedings. At the meeting, the Presidents of the Commissions made the following statements, findings and proposed amendments which were incorporated into the Clean Air Action Plan that was approved by the Commissions:

First, we agree with the demand of many of those who commented on the Plan that there must be measurable goals so the public can have a yardstick to measure progress. So, we propose that we commit to a goal of reducing particulate emissions in 2008 by at least 15% from what it would be without the Plan, ratcheting up each year to at least a 45% reduction in 2011.

Second, we think we need to recognize that ultrafine particles are probably the most damaging of the fossil-fuel related air pollutants to human health. Accordingly, we propose that the staffs of the two Ports be directed to work with the USC Research Group on Ultrafine Particles to present the results and suggested next steps to the two Commissions no later than July 1, 2007. In addition, our new Technology Advancement Program must include ways to eliminate emissions of ultrafine particles, which in reality, in our view, means moving towards carbon-free fuels.

Third, we should recognize that the recently enacted California Global Warming Solutions Act of 2006 (AB32) requires carbon emissions be reduced back to 1990 levels by the year 2020. In light of the growth prospects of the two Ports, that means we must switch to carbon-free fuels (for example, green electricity) and other carbon-free technologies in every possible application as soon as possible. Toward that end, we propose that our respective staffs include such technology in our Technology Advancement Program. As part of that effort, the Ports pledge to contribute, and raise from other interested parties, the many millions needed to fund this vital effort.

Also, there is one technical amendment we offer to make clear that implementation of the individual Plan measures are subject to additional CEQA review, a fact that is beyond dispute and in the interest of all parties. We therefore move that on page 19 of the Overview and page 24 of the Technical Report the three words after "conducted" be stricken and replaced with "subject to CEQA statute, regulations and guidelines".

Both the environmental organizations and the business communities have expressed a desire for a continuous process for participation in the ongoing review and improvement of the Clean Air Action Plan in the months and years ahead. We welcome such participation. We therefore urge ALL groups to provide the Ports, within the next 30 days following adoption of the CAAP [by December 20, 2006], their ideas for how such public participation can best be conducted. We will promptly approve and implement that process within 30 days after receipt and review of their ideas.

A critical initiative in the Plan is a massive effort to deal with the well-recognized problem of heavily polluting trucks driven by under-paid drivers. These trucks produce 10% of the Port-related diesel particulate emissions and fully 25% of the NOx emissions. The Ports have identified over 16,000 individual vehicles that make 80% of the trips to and from Port terminals, so cleaning up those vehicles would eliminate a significant portion of Port-related air pollution.

That will be a hugely expensive effort that will involve replacing many trucks and retrofitting others with pollution control devices. The Commissioners of both Ports believe that we can tackle the dirty truck problem in a manner consistent with the Clean Air Action Plan. Accordingly, we direct our respective staffs to work expeditiously to bring forward a plan with the following elements for further future approval of these boards:

a. The Ports undertake a 5-year, focused effort to replace or retrofit the entire fleet of over 16,000 trucks that regularly serve our Ports with trucks that at least meet the 2007 control standards and that are driven by people who at least earn the prevailing wage.
b. The Ports establish within their respective districts a program that restricts the operation of trucks that do not meet the clean standards established in the Plan. Further, that we impose a system of fees and transportation charges to raise the necessary funds to pay for the cleaner trucks. These fees would be imposed on "shippers", and not on the drivers.
c. The Ports will invite private enterprise trucking companies to hire the drivers on terms that offer the proper incentives and conditions to achieve the Clean Air Action Plan goals while resulting in adequately paid drivers.
d. The Ports begin this program with an infusion of cash to the Gateway Cities Program that would fund a 500-truck program that will demonstrate the applicability of new retrofit technologies. This demonstration program will be activated in the 1st quarter of 2007, and the full 16,800-truck program will be rolled out shortly thereafter.
e. The Ports develop requests for proposals that will encourage truck fleets of alternatively-fueled vehicles, for example, LNG.

We believe that we can count on the support of our private industry and government partners in this effort.

We believe that this program would enable the Ports to achieve one of the major goals of the Clean Air Action Plan quickly and with minimum economic impact to the people who can least afford to absorb extra costs, namely the hard-working truck drivers who move so much of the cargo.

That leads to our second point, which is the issue of monetary incentives. Many people have commented that the Ports need to pay to clean up pollution from Port operations. Both Boards want to make it clear that the Ports cannot and will not subsidize the cost of cleaner transportation indefinitely. Those expenses are a legitimate cost of doing business, and we believe that our position will ensure that companies engaged in goods movement pay their fair share of the cost of cleaning up our air and protecting our citizens. Accordingly, it is our policy that monetary payments by the Ports for cleaner technologies and fuels will be granted to true pioneers in the industry, but only for short periods of time. After that, each entity must bear the costs of reducing pollution from its operations.

FOREWORD

To effectively integrate common goals for air quality in the South Coast Air Basin, the Port of Los Angeles (POLA) and the Port of Long Beach (POLB) have worked together in close coordination with the staff of the South Coast Air Quality Management District (SCAQMD), the California Air Resources Board (CARB), and the United States Environmental Protection Agency Region 9 (EPA Region 9) to develop the San Pedro Bay Ports Clean Air Action Plan. This Plan is the first of its kind in the country, linking the emissions reduction efforts and visions of the two largest Ports in the United States with similar efforts and goals of the regulatory agencies in charge of ensuring compliance with air quality standards. The collaborative effort will continue in the years to come with the review and update of the Clean Air Action Plan on an annual basis.

The air agencies have extensively reviewed and commented on the draft Plan, support the collaborative process that has been established, and support the goals delineated in the Plan. By participating in the development and annual review of this Plan, these regulatory agencies do not waive or forfeit their rights or obligations to continue to regulate emissions sources under their control. Participation in this process is voluntary by all parties and does not in any way inhibit or preclude agencies from any legal authorities and responsibilities to meet federal, state, and local air quality standards. Participation does not mean that the agencies necessarily endorse each of the measures and concepts proposed in the Plan.

WHAT'S IN THE CLEAN AIR ACTION PLAN?

TABLE OF CONTENTS

INTRODUCTION

This document is the first San Pedro Bay Ports Clean Air Action Plan (Clean Air Action Plan). This joint Clean Air Action Plan describes the measures that the Ports of Los Angeles and Long Beach will take toward reducing emissions related to port operations. In March 2006, a groundbreaking meeting occurred at the highest level between the two Ports and the South Coast Air Quality Management District (SCAQMD) where all parties expressed the need to work jointly toward solutions. Shortly thereafter, the Ports engaged the California Air Resources Board (CARB) and the United States Environmental Protection Agency Region 9 (EPA Region 9) in the spirit of cooperation to help the Ports develop the Clean Air Action Plan for their respective Boards of Harbor Commissioners' approval. It should be emphasized that these entities have committed to continuing their efforts associated with the development, review, implementation, and update/revision of the Clean Air Action Plan on an annual basis.

The five-year Action Plan highlights the goals, emissions reductions, and budgetary needs for fiscal years (FY) 2006/2007 through 2010/2011. By the end of the five-year period, virtually all needed measures to meet the goals will be in place. Staff from both Ports intend to regularly evaluate progress towards meeting the Clean Air Action Plan goals, review status of existing control measures, evaluate new measures, and jointly develop a revised action Plan each year.

THE HISTORY

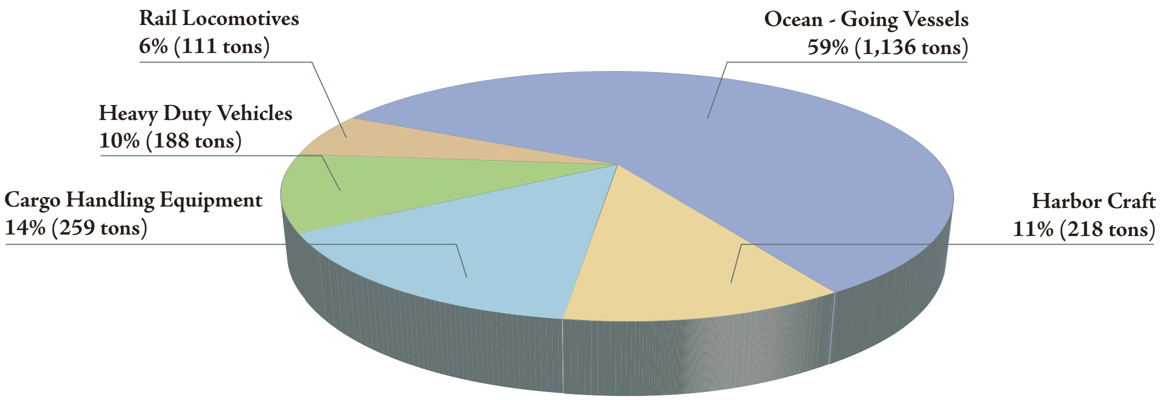
In the early 1900s, the State conveyed the Port tidelands to Los Angeles and Long Beach, as trustees for the people of the State of California, to accommodate and promote harbor commerce, navigation and fisheries. The Ports are landlord ports; they build terminal facilities and lease them to shipping lines and stevedoring companies. The Ports do not operate the terminals, ships, yard equipment, trucks or trains that move the cargo. However, the Ports are determined to accelerate the effort to reduce air pollution from "goods movement" activities using all the powers available to them.

The San Pedro Bay Ports (SPBP) comprise a huge regional and national economic engine. The Los Angeles Customs District accounts for approximately $300 billion in annual trade. More than 40% of all containerized trade in the nation flows through the SPBP. Economic forecasts suggest that the demand for containerized cargo moving through the San Pedro Bay region will more than double by the year 2020.

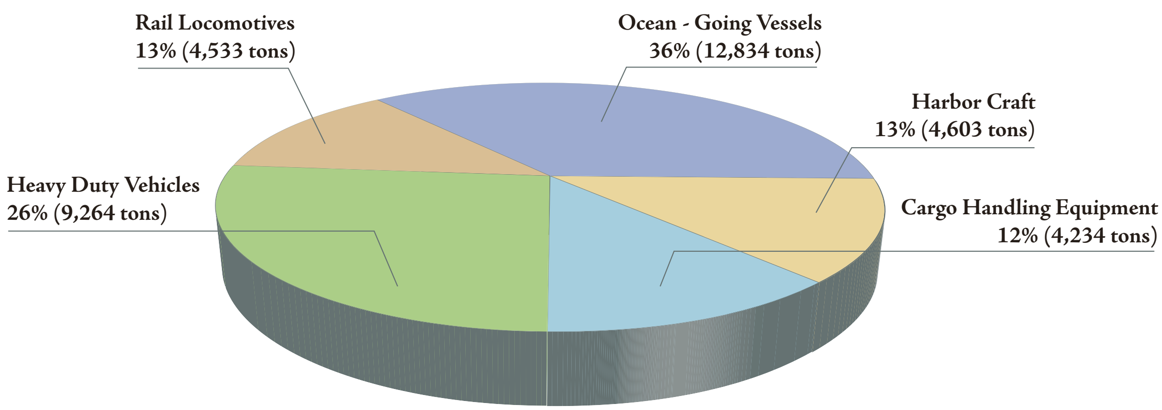
PORT-RELATED EMISSIONS

Based on the baseline year emissions inventories for both Ports (2001/2002), the contribution of emissions by the five port-related source categories, and their percentage share compared to the South Coast Air Basin (SoCAB), are presented in following figures.

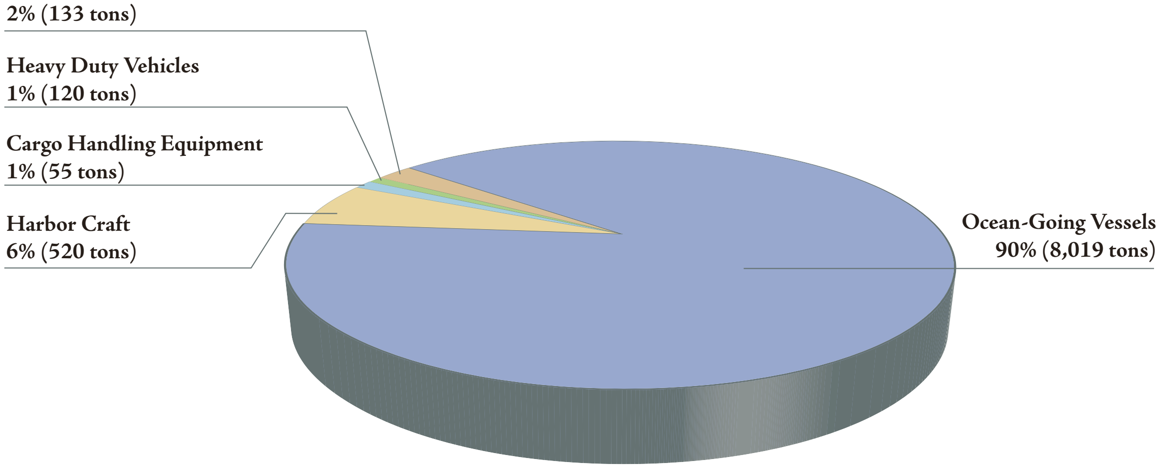
Baseline Year DPM Emissions Contributions by Source Category



Baseline Year NOx Emissions Contributions by Source Category

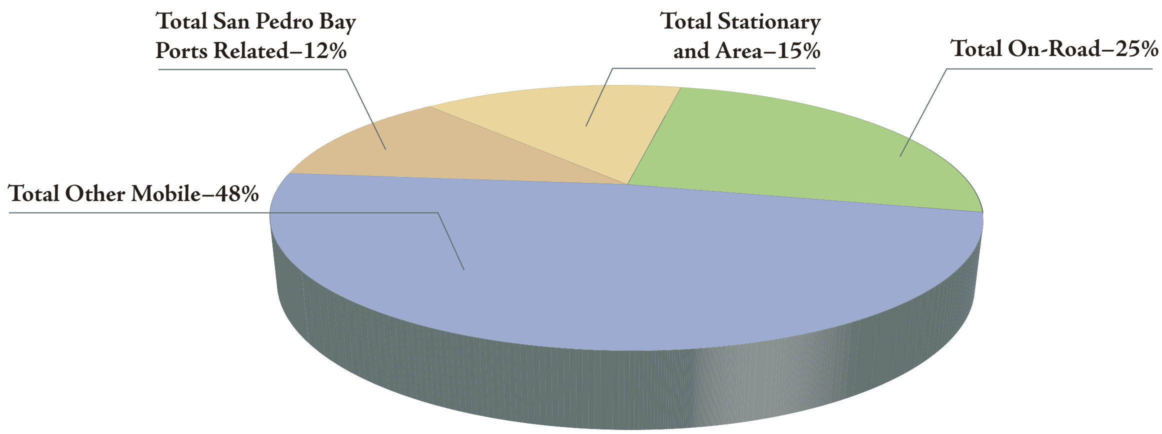


Baseline Year SOx Emissions Contributions by Source Category

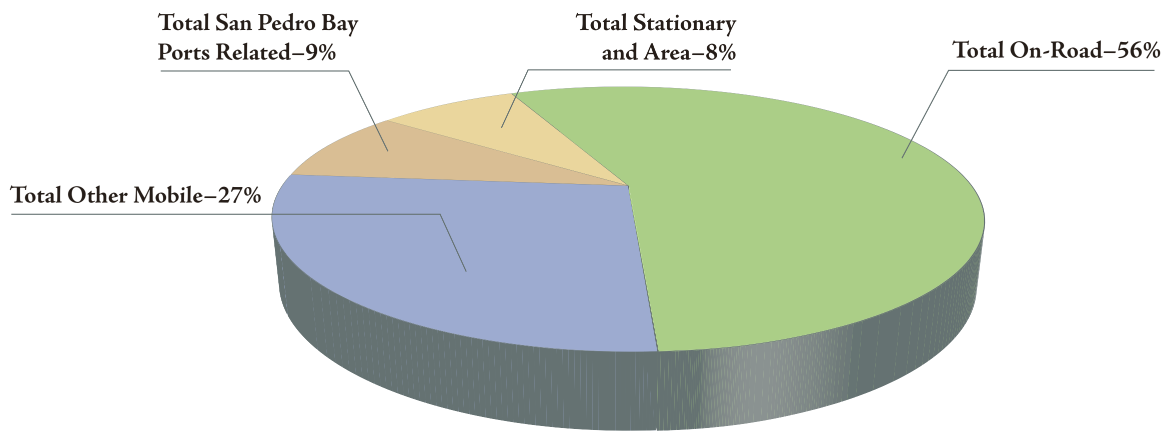


The following figures compare the San Pedro Bay Port percentage contributions, with the contributions from all the emissions sources in the SoCAB for the baseline year.

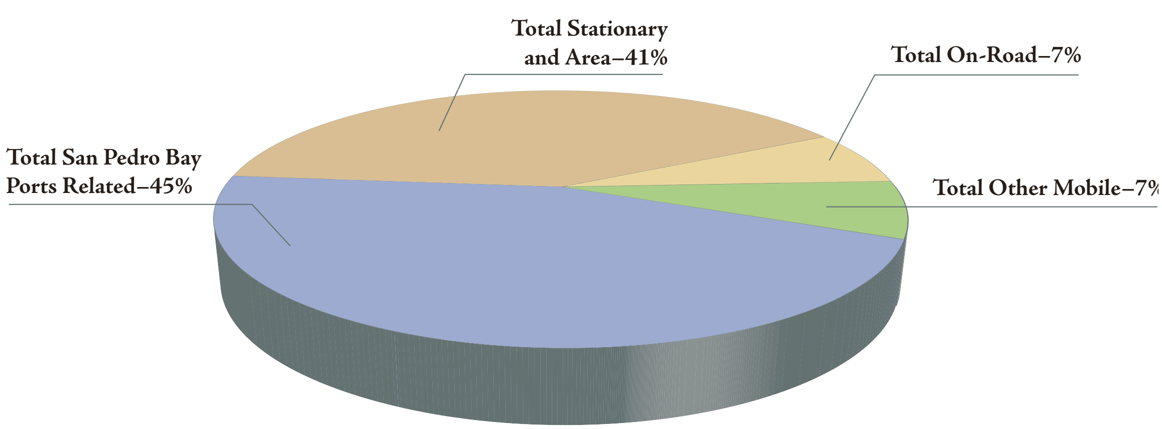
Baseline Year SPBP vs. SoCAB DPM Emissions Contributions



Baseline Year SPBP vs. SoCAB NOx Emissions Contributions



Baseline Year SPBP vs. SoCAB SOx Emissions Contributions



The Ports and regulatory agencies acknowledge that if port-related sources are not controlled by the Clean Air Action Plan to reduce their "fair share" with respect to the other sources in the SoCAB, port-related contributions to the basin's total emissions (particularly with respect to OGVs) will increase significantly beyond the levels presented above. Therefore, action must be taken now in order to help the basin meet its air quality goals.

Table 4.1: Guideline values for community noise in specific environments.

Specific environment	Critical health effect(s)	LAeq [dB]	Time base [hours]	LAmax, fast [dB]
Outdoor living area	Serious annoyance, daytime and evening Moderate annoyance, daytime and evening	55 50	16 16	- -
Dwelling, indoors Inside bedrooms	Speech intelligibility and moderate annoyance, daytime and evening Sleep disturbance, night-time	35 30	16 8	 45
Outside bedrooms	Sleep disturbance, window open (outdoor values)	45	8	60
School class rooms and pre-schools, indoors	Speech intelligibility, disturbance of information extraction, message communication	35	during class	-
Pre-school bedrooms, indoors	Sleep disturbance	30	sleeping -time	45
School, playground outdoor	Annoyance (external source)	55	during play	-
Hospital, ward rooms, indoors	Sleep disturbance, night-time Sleep disturbance, daytime and evenings	30 30	8 16	40 -
Hospitals, treatment rooms, indoors	Interference with rest and recovery	#1		
Industrial, commercial shopping and traffic areas, indoors and outdoors	Hearing impairment	70	24	110
Ceremonies, festivals and entertainment events	Hearing impairment (patrons:<5 times/year)	100	4	110
Public addresses, indoors and outdoors	Hearing impairment	85	1	110
Music through headphones/ earphones	Hearing impairment (free-field value)	85 #4	1	110
Impulse sounds from toys, fireworks and firearms	Hearing impairment (adults) Hearing impairment (children)	- -	- -	140 #2 120 #2
Outdoors in parkland and conservation areas	Disruption of tranquillity	#3		

#1: as low as possible;
#2: peak sound pressure (not LAmax, fast), measured 100 mm from the ear;
#3: existing quiet outdoor areas should be preserved and the ratio of intruding noise to natural background sound should be kept low;
#4: under headphones, adapted to free-field values

GUIDELINES FOR COMMUNITY NOISE

Edited by

Birgitta Berglund
Thomas Lindvall
Dietrich H Schwela

This WHO document on the *Guidelines for Community Noise* is the outcome of the WHO-expert task force meeting held in London, United Kingdom, in April 1999. It bases on the document entitled "Community Noise" that was prepared for the World Health Organization and published in 1995 by the Stockholm University and Karolinska Institute.

World Health Organization, Geneva
Cluster of Sustainable Development and Healthy Environment (SDE)
Department for Protection of the Human Environment (PHE)
Occupational and Environmental Health (OEH)

Environmental Justice Community Noise Standard

1. Environmental Justice Community Noise Standard

Environment	Day 7:00am – 5:00pm	Night 5:00pm-7:00am	Night Sleep Time 9:00pm – 7:00am
Outdoor	50dBA	40dBA	
School Indoor	35dBA	35dBA	
Preschool Sleep Time	30dBA		
Residence Indoor	35dBA	35dBA	
Residence Indoor Sleep Time			30dBA
Residence Indoor Low Frequency			25dBA

1.1 General Ambient Noise Level

Los Angeles Noise Ordinance – Chapter XI Noise Regulation, Article 1 General Provisions Sec. 111.00 Declaration of Policy and Sec. 111.03 Minimum Ambient Noise Level Table II Zone A1, A2, RA, RE, RS, RD, RW1, RW2, R1, R2, R3, R4, R5 Presumed Ambient Noise Level Day dBA 50 and Night 40dBA and Article 6 General Noise Sec.116.01 Loud, Unnecessary and Unusual Noise.

3.3 Community Ambient Noise Protection

World Health Organization – Guidelines for Community Noise, Table 1 & Table 4.1 Guidelines Values for Community Noise in Specific Environments – Specific Environment: Inside Bedrooms 30dBA, Preschool Sleep 30dBA and School Class Rooms 35dBA.

3.4 Specific Low Frequency Noise Protection

World Health Organization – Guidelines for Community Noise, 4.2.3 Sleep Disturbance Effects states, "For noise with a large proportion of low frequency sounds a still lower guideline lower than 30dBA is recommended," and "Since A-weighting underestimates the sound pressure level of noise with low frequency components, a better assessment of health effects would be to use C-weighting."

3.5 American Industry Standard

The American National Standards Institute (ANSI) ANSI S12.60-2002 Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools, Table 1 pg. 5 for Learning space 35dBA.

4.0 Technical Approach

Community On-Site Monitoring Technical Approach TBD.

5.0 Real Time Ambient Noise Level Monitoring

5.1 Real Time Ambient Noise Level Monitoring shall as a minimum measure Leq, L10, Ldn, Lmax, SEL and CNEL. A-Frequency Weighting and C-Frequency Weighting shall be monitored and recorded.

5.2 All measurements must be continuous and recorded.

6.0 Real Time Noise Sound Recording

6.1 Real time ambient noise shall be recorded to determine source and types of noises.

6.2 Noise sound recording will be continuous non-stop recording either analog or digital 24hrs. per day with digital preferred.

7.0 Noise Sound Level Meter

7.1 The Noise Sound Level Meter shall be a Type I to ANSI S1.4-1998 or most recent revision.

7.2 A Sound Level Meter with data-logging capability for recording a minimum of 24 hrs. continuously recording and 7 days non-stop is preferred.

7.3 A Sound Level Meter capable of recording ambient noise sound a minimum of 24 hrs. continuously and 7 days non-stop is preferred.

7.4 Sound Level Meters, Data Logging and Sound Recording Equipment and accessories must be capable of withstanding outdoor inclement weather.

8.0 Noise Monitoring Locations

Locations TBD.

9.0 Noise Monitoring

Protocol TBD

10.0 Noise Monitoring Schedule

Schedule TBD.

11.0 Frequency of Noise Monitoring

11.1 Measurements shall as a minimum be every 15 minutes for 24hrs. per day or as may be determined necessary.

12.0 Equipment Calibration

12.1 Equipment calibration shall be traceable to the National Bureau of Standards and the American National Standards Institute (ANSI) S1.4-1998 or most recent revision.

12.2 Records shall be maintained and provided upon request.

13.0 Equipment Inspection & Monitoring

On-Site Equipment Inspection & Monitoring Plan TBD.

14.0 Record Keeping Procedures

Procedures TBD.

15.0 Noise Monitoring Quality Assurance

QA Plan TBD.

16.0 Noise Monitoring Reports

Noise Monitoring Reports will be produced monthly, quarterly and annually.

17.0 Data Analysis & Review

Format TBD.

18.0 Corrective Action

CA TBD.

NOISE CONTROL ACT OF 1972

HISTORY: Public Law 92-574, Oct. 27, 1972; 86 Stat. 1234; 42 USC 4901 et seq.; Amended by PL 94-301, May 31, 1976; PL 95-609, Nov. 8, 1978; PL 100-418, Aug. 23, 1988

SEC. 1 [42 U.S.C. 4901 nt], Short Title.

This Act may be cited as the "Noise Control Act of 1972."

SEC. 2 [42 U.S.C. 4901]Findings and Policy.

(a) The Congress finds--

(1) that inadequately controlled noise presents a growing danger to the health and welfare of the Nation's population, particularly in urban areas;

(2) that the major sources of noise include transportation vehicles and equipment, machinery, appliances, and other products in commerce; and

(3) that, while primary responsibility for control of noise rests with State and local governments, Federal action is essential to deal with major noise sources in commerce control of which require national uniformity of treatment.

(b) The Congress declares that it is the policy of the United States to promote an environment for all Americans free from noise that jeopardizes their health or welfare. To that end, it is the purpose of this Act to establish a means for effective coordination of Federal research and activities in noise control, to authorize the establishment of Federal noise emission standards for products distributed in commerce, and to provide information to the public respecting the noise emission and noise reduction characteristics of such products.

SEC. 3 [42 U.S.C. 4902] Definitions.

For purposes of this Act:

(1) The term "Administrator" means the Administrator of the Environmental Protection Agency.

(2) The term "person" means an individual, corporation, partnership, or association, and (except as provided in sections 11(e) and 12(a)) includes any officer, employee, department, agency, or instrumentality of

AECOM

GENERAL ATOMICS ELECTROMAGNETIC SYSTEMS

Proprietary Information

Value Proposition / Public Health-Public Safety

- Reduction of energy costs as diesel fuel is twice as costly per energy unit than electricity from a stationary power plant.
- Reduces costs to move containers out of Long Beach/LA Ports making our ports more competitive nationally creating more jobs
- Reduction of pollution as diesel engines produce 120 to 240 times more particulate pollution and NOX than a stationary power plant.
- Reduction of costs to the public of lost time, wages and health resulting from the effects of pollution, thereby increasing public health benefits.
- Low installed cost , low operating and maintenance costs

Only 1 vehicle at a time on track section: No chance of collision

Calculation of Linear Motor Fuel Savings

- Operating assumptions
  - 10-mile route with 1 million cargo cars/year
  - 50 tons/car → 500 million ton-miles of traffic per year
- Diesel fuel cost (conventional locomotives)
  - 400 ton-miles/gallon fuel over 500 million miles = 1.25m gal/yr
  - 1.25 million gal/year x $2.30/gal = <u>$2.87M/year diesel fuel cost</u>
- Electricity cost (LIM/LSM)
  - 0.5 lb diesel/Hp-hr → 14 Hp-hr.gal → 10.6 kWhr/gal
  - 400 ton-miles/gal over 500 million miles = 13.3m kWhr
  - 13.3M kWhr x $0.12/kWhr = <u>$1.596M/year electricity cost</u>

Calculation of Linear Motor NOx Reduction

- Same operating assumptions (500 million ton-miles/year of traffic)
- NOx emissions (conventional locomotives)
  - 202 g NOx/gallon fuel x 1.25 m gal/yr = 252.5m g NOx/yr
  - 252.5M g NOx/year = 278 tons NOx/year
- NOx emissions (Linear Motor Rail)
  - 0.15 lb NOx/MWhr (2000 SCE power plant rule)
  - 0.15 lb NOx/MWhr x 13,300 MWhr/year = 1,995 lb NOx/year
  - 1,995 lb NOx/year = 1 ton NOx/year
- That's 278 Tons vs. 1 Ton over a single 10 mile stretch of rail

Market Potential

- **Freight**
  - Railroads
  - Trucks
  - Port terminals
  - Intermodal railyards
- **Passenger Rail**
  - Metro
  - Light Rail
  - Commuter Rail
- **Autos / Trucks / Buses**
  - Auto lanes
  - Truck lanes
  - Bus lanes

LSM Drive Characteristics
Preliminary Analysis - The Virtual train

- Independent remote or on board control of each vehicle
- Magnetic propulsion and regenerative braking reduces energy cost by as much as 75% under certain operating conditions.
- Only one vehicle allowed per track section – collisions impossible.
- Reliable
  - No moving parts – Reduced maintenance, energy and operating costs.
- Force is applied directly to vehicle
  - Reduces wear on wheels and rails
  - High performance (acceleration, velocity)→ High Throughput
- Complete control over acceleration and velocity
- Quiet – no engine noise.
- Capital cost comparable to electric overhead conversion

Maglev Train - Existing Maglev Systems

Maglev Train - Birmingham 1984–1995

The world's first commercial automated system was a low-speed maglev shuttle that ran from the airport terminal of Birmingham International Airport (UK) to the nearby Birmingham International railway station from 1984 to 1995. The length of the track was 600 m, and trains "flew" at an altitude of 15 mm. It was in operation for nearly eleven years, but obsolescence problems with the electronic systems made it unreliable in its later years and it has now been replaced with a cable-drawn system.

Maglev Train - Berlin 1989–1991

In West Berlin, the M-Bahn was built in the late 1980s. It was a driverless maglev system with a 1.6 km track connecting three stations. Testing in passenger traffic started in August 1989, and regular operation started in July 1991. Although the line largely followed a new elevated alignment, it terminated at the U-Bahn station Gleisdreieck, where it took over a platform that was then no longer in use; it was from a line that formerly ran to East Berlin. After the fall of the Berlin Wall, plans were set in motion to reconnect this line (today's U2). Deconstruction of the M-Bahn line began only two months after regular service began and was completed in February 1992.

Maglev Train - Transrapid

Transrapid, a German maglev company with a test track in Emsland, constructed the first operational high-speed conventional maglev railway in the world, the Shanghai Maglev Train from downtown Shanghai, China to the new Shanghai airport at Pudong. It was inaugurated in 2002. The highest speed achieved on the Shanghai track has been 501 km/h (311 mph), over a track length of 30 km. Transrapid uses EMS technology.

Maglev Train - JR-Maglev

Japan has a test track in Yamanashi prefecture where test trains JR-Maglev MLX01 have reached 581 km/h (363 mph), faster than wheeled trains. These trains use superconducting magnets which allow for a larger gap, and repulsive-type "Electro-Dynamic Suspension" (EDS). In comparison Transrapid uses conventional electromagnets and attractive-type "Electro-Magnetic Suspension" (EMS). These "Superconducting Maglev Shinkansen", developed by the Central Japan Railway Co. ("JR Central") and Kawasaki Heavy Industries, are currently the fastest trains in the world, achieving a record speed of 581 km/h on December 2, 2003.

Updated Economic Impact Study Shows That Ports of Los Angeles, Long Beach and Alameda Corridor Remain Vital to U.S. Economy and International Trade

Thursday March 22, 11:50 am ET

Study Finds $256 Billion of Containerized Trade and Over 3.3 Million Jobs Nationwide Connected to the Ports of Los Angeles and Long Beach

LOS ANGELES--(BUSINESS WIRE)--A comprehensive trade impact study released today by the Alameda Corridor Transportation Authority (ACTA) and the San Pedro Bay ports of Los Angeles and Long Beach reinforces the agencies' critical role in international trade and the economic benefits Southern California's Pacific trade gateway provides to the entire nation. In particular, this detailed study reveals the economic benefits that exported and imported goods moving through the nation's two largest container ports and the Alameda Corridor have for every region across the country.

The San Pedro Bay ports handle more than 40% of the nation's total import traffic and 24% of its total exports. From the machinery, raw materials, cotton and other goods being shipped overseas to the clothing, toys, and other products coming into the country, thousands of exporters and importers across the country rely on these ports as their primary gateway for trade. Since 1994, when this trade impact study was first conducted, the growth in the national impact of trade for goods being transported the San Pedro Bay ports increased 246%, from $74 billion to $256 billion.

"Southern California is America's Gateway to the global economy and plays a central role in sustaining the nation's prosperity," said Los Angeles Mayor Antonio Villaraigosa. "As container traffic continues to grow, however, we must invest more in our goods movement infrastructure while addressing the environmental and health impacts of our ever-expanding international trade."

"The study re-affirms the national significance of the San Pedro Ports. These two ports lead the way not only in cargo volumes but in implementing forward-thinking environmental mitigation strategies that recognize the severe health impacts on our communities of such monumental commerce," said Long Beach Mayor Bob Foster.

The study also assessed the economic impact of the San Pedro Bay ports in terms of state and local tax revenues and full-time jobs created. State and local taxes generated throughout the nation from this trade activity grew from an estimated $6 billion in 1994 to more than $28 billion in 2005. The number of direct and indirect jobs associated with the trade activity generated by the San Pedro Bay ports increased by 200%, from 1.1 million jobs nationally in 1994 to 3.3 million jobs in 2005.

National Trade Activity Segmented by Region

In addition to assessing the national impacts of trade activity at the San Pedro Bay ports, the study also examined the economic value of this trade in various regions of the country. Of the $256 billion in total national trade activity, the regions which show the greatest reliance on Southern California's ports include: the Southwest region ($82 billion in imports and exports); the Great Lakes region ($53.7 billion); the Southeast region ($37.7 billion); and the South Central region ($27.3 billion). Similar analyses was conducted to determine the jobs associated with this trade in each region, with the Southwest (1,114,400 jobs), Great Lakes (681,800), Southeast (498,900), South Central (435,700), and Northwest (339,900) leading the way.

America's Goods Movement Corridor

As the first link in the national rail system leading out of the San Pedro Bay ports, the Alameda Corridor has seen 106% growth in cargo movement over the last four years; more than double that of the ports' growth during that time. More than 60% of the cargo which arrives at the San Pedro Bay ports is ultimately destined for markets outside of Southern California, and a large portion of that cargo is handled by the 20-mile Alameda Corridor. In 2006, the Alameda Corridor carried 19,924 trains, an average of 55 trains per day. This represents a 15% increase over the number of trains which used the Corridor in 2005. In addition, nearly 5 million Twenty-foot Equivalent Units (TEUs) were transported via the Corridor in 2006, a 32% increase from the 3.75 million TEUs moved on the Corridor in 2005. On an average day, the Alameda Corridor carries 14,000 TEUs of cargo, more than twice the entire daily volume of cargo that is handled by the Port of Oakland.

With more than $256 billion in containerized trade moving through the San Pedro Bay ports in 2005, this study illustrates the need for a continued federal and state commitment to supporting and improving Southern California's goods movement infrastructure network. The results of this latest economic study also serve to further demonstrate the critically important role that the Alameda Corridor plays in the national economy as the linchpin to the goods movement network.

The Port of Los Angeles, a non-taxpayer-supported department of the City of Los Angeles, and the Port of Long Beach, a non-taxpayer supported department of the City of Long Beach, are the top two container seaports in America. Together, the ports occupy about 7,400 acres of land, 7,900 acres of water and 78 miles of waterfront in Southern California. With about 60 (combined) terminals serving container, automobile, break bulk, liquid bulk and dry bulk customers, the ports facilitate the flow of goods that sustain the entire nation. In addition to leading the nation in international cargo trade, the San Pedro Bay Ports are dedicated to leading the world in progressive and aggressive environmental programs. In November 2006, at a first-ever joint meeting of the two Harbor Commission Boards, the San Pedro Bay Ports Clean Air Action Plan was adopted. This landmark plan, the first in maritime history, outlines a strategy for reducing air emissions at both ports by roughly 50 percent over a five year period.

LA-area ports to study magnetic levitation cargo train

Associated Press

LOS ANGELES - Harbor officials are planning to study whether magnetic levitation trains could be used to ferry cargo containers moving through the nation's largest port complex.

The so-called maglev trains are seen as a possible way to ease traffic congestion and cut down on air pollution near the Ports of Los Angeles and Long Beach.

Researchers at California State University, Long Beach, are studying three proposals for using maglev trains to move cargo.

The Southern California Association of Governments and officials at the two ports are planning to launch their own studies in coming months.

"If we are going to get serious about cleaning up the port, we need to bring electric power into the transportation system. We need to be emission-free if we are going to grow," said S. David Freeman, president of the Los Angeles Harbor Commission. "Maglev is one of several options we are looking at. It has a lot going for it."

Maglevs are propelled along magnetic fields generated by guide rails on the ground. They can reach speeds of up to 300 mph.

Two maglev train systems transporting passengers are operating in China and Japan.

No one has yet to adapt the maglevs to carry freight, however.

General Atomics in San Diego is developing a system for cargo containers.

Among the maglev projects being studied is a 4.7-mile system between the Port of Los Angeles and the proposed Southern California International Gateway, a rail terminal to the north.

Building the project would cost roughly $575 million and $9.2 million a year to operate.

A 100-mile maglev network linking inland cargo distribution centers to the ports is projected to cost around $8.5 billion.

Another maglev proposal under review involves a 20-mile line running by the Long Beach Freeway.

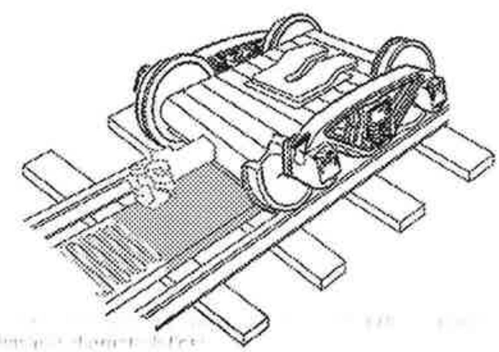
Port Container Moving System

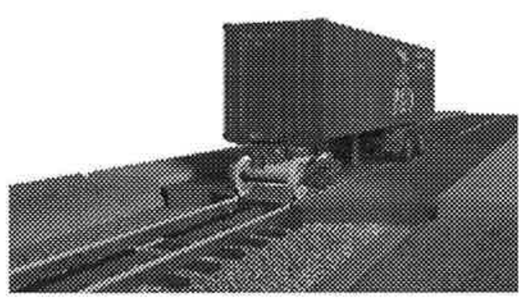
The Zero Emissions System

This system will have the following characteristics:

- *Independent remote or onboard control of each vehicle*
- *Magnetic propulsion and regenerative braking reduces energy consumption by as much as 75% under certain operating conditions* — NO EVIDENCE
- *Only one vehicle per track section -- collisions impossible* — hardly - it's the trailers
- *Reliable: No moving parts, reduced maintenance* — contrary to act exper.
- *Complete control over acceleration and velocity* — caveat
- *Quiet -- No engine noise* — also may true
- *Capital cost comparable to electric overhead conversion* — see spec

Freight transport by train is the most economical way to move large amounts of freight for long distances. However, the movement of massive amounts of goods through Ports using diesel locomotives is highly polluting and getting worse as freight train traffic has doubled in the last 35 years. The Environmental Protection Agency estimates that combined emissions from Diesel trains in Chicago, Los Angeles, Houston, Dallas, Baltimore and Detroit is equal to the emissions created by 55 million cars meeting today's automotive emission standards. This amounts to 37% of all automobiles driven in the United States today





The goal of the Zero Emissions Port Container Moving System is to use linear motor rail conversion to develop the next step in the evolution of railcars to a near zero emissions electric propulsion system a lower energy and capital cost which is fully automated. It is estimated that this goods transport method will produce between 1/150 and 1/250 the amount of pollution as existing methods, at 1/3 the f cost.

By simply installing a diesel truck fifth whe on the top of the magnetically fitted bogey and paving the LSM track, similar to a street car operation in urb streets, the port container moving systems becomes a reality.

MagneRail™ Linear Motor Technology

MagneRail™ is an innovative transportation concept based on the idea of retrofitting conventional steel-wheel rail lines with linear synchronous motors, most likely mounted to the railroad ties between the rails. By creating moving magnetic fields within the linear motors, rail cars could be propelled "passively" by mounting permanent magnets to the undercarriages of the vehicles. The force created by the track-mounted linear motor would react against the permanent magnets, forcing the vehicles to move in the direction of the moving magnetic field. In an early MagneRail™ concept, pictured above, existing locomotives would be retrofitted with permanent magnets, enabling them to pull rail cars on linear motor rail segments without using their diesel engines. More recent MagneRail™ concepts feature a specially-designed magnetic "power car" that would not use engines or any active onboard propulsion. Such a lightweight, rolling rail chassis equipped with permanent magnets would be optimized to operate on track equipped with linear motors, and would cost a fraction as much to build and operate as a conventional locomotive.

GA has entered into a Teaming Agreement with Innovative Transportation Systems Corp. (ITSC), a San Diego transportation project management firm, to develop and market MagneRail™ systems customized for a variety of applications, including:

- Goods movement – MagneRail™ power cars could tow cargo containers between ports and intermodal container transfer facilities.
- Commuter rail – MagneRail™ technology could be used to magnetically propel commuter trains and other light rail systems, either by retrofitting existing rail cars with magnets or by developing new passenger vehicles designed specifically to operate on linear motor rail segments using permanent magnets.
- Street cars – By embedding rails and the linear motors between the rails in flat pavement, street-cars using either steel wheels on rail or rubber tires could be propelled using MagneRail™ technology.

Features

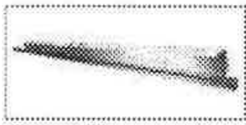
Linear Induction Motor

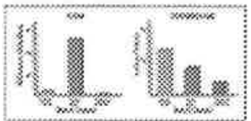
- Mounted to existing railroad tracks.
- Generates moving magnetic field that can be regulated to control vehicle acceleration and speed.
- Completely safe – sheathed in hard plastic and motor sections are energized only when trains pass over.
- No need for electrified third rails or overhead catenary lines

Vehicle

- Aluminum reaction plate mounted to underside of vehicle reacts against linear motor and moves vehicle forward.

- In lieu of the aluminum plate, an array of permanent magnets can be used, providing greater efficiency.
- Existing rail vehicles can be retrofitted, or new design vehicles can be built





Other Applications

- Light passenger rail.
- Commuter rail.
- Can be installed into specific sections of track, e.g., near passenger stations to reduce emissions and noise in populated areas.

MAGLEV vs. TRAIN COMPARISONS

The traditional passenger rail industry and the Federal Railroad Administration shamelessly claim that steel-wheel-on-steel-rail mechanical train technology is superior to, or at least as good as, electronic non-contact maglev transport technology. NAMTI categorically denounces such false and transparent public relations efforts.

Maglev can be best characterized as electronic flight. Maglevs are not trains. Trains are trains and are highly maintenance intensive, unlike non-contact maglevs.

The videos in this section provide visual and audio proof to back up our position. As you will see, some of these comparisons are amusing or laughable.

Building the best public transportation available is anything but funny because of its lasting impact on the nation's economy. That is why NAMTI is so intent upon educating the North American public about how their kids' future is being sold short by existing transportation policies and the efforts of passenger rail lobbyists.

We must tell our political representatives to upgrade or replace those federal and state agencies that doggedly hang onto old, maintenance intensive and subsidy-dependent mechanical transit systems that are clearly not economically sustainable.

Just click on the the thumbnail images below to see and hear the difference between these radically different technologies.

ABSTRACT

A critical review of maglev trains and convention wheeled trains was presented in an attempt to identify performance advantages of maglev. Traditionally claimed advantages of maglev were not found to hold up to wheeled train systems incorporating similar non-contacting propulsion; however, performance advantages were identified for velocities greater than 500 mph (805 km/hr). At these high velocities, travel at atmospheric pressure is not practical, and so, an analysis was made for applications in tubes of reduced pressures.

The feasibility of a personal rapid transit (PRT) system designed with maglev suspension and for travel in tubes of reduced pressure was evaluated. The PRT maglev would have superior service capabilities yet no obvious technological barriers. An economic comparison to maglev train systems suggested that the PRT maglev costs about 40% less while providing appeal to a broader audience. Proposed performance advantages of the PRT maglev include reduced energy consumption, reliance on electrical power, and significantly reduced transit times as compared to air or train systems. A practical approach to implementation is presented and consists of initially using lower velocities, higher tube pressures, and PRT vehicles connected as train units. Proposed evolution of the system includes attaining higher velocities and incorporating superconductive elements in the rail embodiments.

Key Words: Maglev, PRT, Train, High Speed, Vacuum

A REVIEW OF MAGLEV TECHNOLOGY

As noted by Sinha (1), it was only in the 1960's that fast electromechanical control gears and the advent of solid state electronics made maglev vehicles feasible. In 1958 Polgreen (2) filed for one of the first maglev patents on a maglev transit system based on repulsion between permanent magnets on the vehicle and along the guideway. Shortly thereafter, Silverman (3) filed for a patent based on attractive levitation using overhead rails and preferably electromagnets on the vehicle. These patents largely specify the genesis era of maglev transit during the late 1950's and early 1960's.

While systems could be conceived during the early 1960's, it was only in the later 1960's when technical issues such as stable suspension, low speed switching, and manageable rail tolerances made maglev transit a practical reality. Powell (4) led the way in truly feasible systems with the unprecedented introduction of (1) inductive suspension allowing vehicle-rail gaps in excess of three inches, (2) electrodynamic lateral stability, (3) incorporation of superconducting magnets, and (4) non-contact propulsion via jet engines. During this second, pragmatic era other significant advances were also made on switching (low speed) without moving parts (5, 6), linear induction motors which would allow the engine noise and fuel weight to be removed from the train (7, 8) and control methods for stable suspension (9, 10).

These and other advances led to several maglev demonstration projects (11) in the early 1980's. Throughout the 1980's attractive EMS suspension systems were advanced in Germany, and repulsive suspension (EDS) systems were advanced in Japan. During this same time period no significant projects were sponsored by the U. S. government. EDS system technology developed during this era is currently being offered for sale by the HSST Corporation of Japan .

The latest era of maglev transit in the United States is perhaps best described as the romantic era due to our governments romance with an idea of advanced transit over a cushion of air and without wheels. The funding made available in the early 1990's was politically motivated by a desire to regain superiority in this intriguing technology. The most significant production from this romantic era are the maglev system cost estimates reported in the Compendium of Executive Summaries from the Maglev System Concept Definition. Final Reports (12). While several U. S. markets consider implementing maglev train systems, no routes greater than a few miles appear to be in the near future.

MAGLEV SUSPENSION VERSUS WHEELED SUSPENSION

Cited advantages of maglev trains over wheeled trains (1, 12) include:

1) Wheels produce medium to high environmental noise levels.

RR inf @ low speed superior @ high speed

2) Wheeled systems rely on propulsion through wheel-rail friction, and the high aerodynamic drag forces lead to upper speed limits due to limited wheel-rail adhesion.

3) Maglev vehicles can accelerate and decelerate rapidly and bank steeply on curves.

4) Suspension through point contact (up to 70,000 psi or 482 MPa) leads to increased structural requirements and increased wear/maintenance.

5) Maglev trains have a certain romantic appeal.

Alternatively, advocates of wheel based trains justify high speed wheel based systems due to an already extensive rail network.

Already existing rail networks give merit to continuing with wheel based systems. However, as discussed subsequently, several cited advantages of maglev have a weak foundation.

While wheels are generally noisier than magnets, at high travel velocities aerodynamic noise greatly exceeds that from wheels (personal conversation with J. Harding, former director of U.S. Maglev Initiative, July, 1993). In perspective, minimal noise reductions are achieved by high speed maglev.

In a similar comparison of propulsion systems, linear synchronous motors (LSM) are capable of overcoming greater aerodynamic drag than wheels and have greater acceleration and deceleration capabilities than wheels. This non-contacting propulsion can be used with wheeled suspension and maglev systems alike. Combinations of LSM propulsion with wheeled suspension would provide needed propulsion without the expense of an entirely new rail system. The Detroit Metro already uses non-contacting linear induction motors (LIM) for propulsion (13, 14). Among its many advantages over conventional wheel propulsion are lighter weight vehicles, reduced height of train cars (15), and improved traction at all weather conditions, velocities, and grades. Figure 1 shows how the LSM propulsion system of the Magneplane concept (12) can be readily incorporated into the vehicles and tracks of a conventional train system. Cited advantages 2) and 3) are specific to LSM propulsion, not maglev suspension, and can be attained by wheeled and maglev systems alike.

An analysis of maintenance costs is simplified when making the assumption that maintenance costs are directly proportional to the weight of the vehicle. Such an assumption would be exact for a hypothetical system designed to have the exact same weight on all wheels, and where reductions in weight would result in eliminating some wheels.

For wheeled propulsion additional weight is advantageous to provide needed traction; however, lighter weight vehicles would be preferred with LSM propulsion. A 70% reduction is vehicle weight would be feasible (1) and would result in 70% reductions in maintenance costs. Furthermore, the application of high performance polymers and shock absorbers incorporating magnetic forces could further reduce maintenance costs.

Public perception be as it may, maglev trains will tend to have a romantic appeal. The romantic appeal and several successful demonstrations of maglev train systems make maglev trains a real alternative. However, for typical applications the slightly higher cost of maglev train systems and advantages of using exiting routes for wheeled alternatives have given the edge to wheeled systems.

In summary, maglev trains have limited advantages and significant disadvantages when compared to high speed wheeled trains using the latest non-contacting propulsion technology. To that end, the most advantageous applications of maglev appear not to be with conventional train systems. Alternatively, transit in low pressure environments and transit by personal rapid transit vehicles (PRT's) are two applications where maglev appears to have performance advantages.

USE OF PRT VEHICLES FOR INTERCITY TRAVEL

While in 1992 PRT concepts were considered dead, the funding of the PRT2000 (16) demonstration may revive the expectations of PRT systems (17). In particular, PRT systems would have advantages of 1) reducing traffic congestion through automation, 2) reducing travel time by providing service non-stop from origin to destination, 3) reducing travel time by having access to a continuous supply of vehicles rather than periodic, and 4) relying upon electrical energy.

Disadvantages (personal conversation with J. Perkowski, Bechtel, San Francisco, May, 1994) identified during the 1970's included 1) performance limitations of available control technology, 2) perceived high cost of the extra number of vehicles, 3) distasteful appearance inside cities, and 4) potentially poor ride quality due to routing problems. Of these disadvantages, advances in electronics since the 1970's should alleviate questions on control technology and mass production of smaller vehicles actually costs little more than the production of fewer large vehicles. In particular, modern RIM polymer technology has gone a long way in reducing costs for vehicles produced in lower quantities. Remaining disadvantages on appearance and routing are design specific.

Routing is made easier and more accommodating due to the small cross-sectional areas of the PRT tubes as illustrated by a comparison of the PRT structure to the Bechtel concept (12) structure. The over-under arrangement of Figure 2 could be made even more accommodating by separating the bi-directional tubes when necessary for routing. Single vehicle tubes of six feet diameters could actually go through buildings. The low pressure environment and maglev suspension reduce noise levels and make such routing practical. Tube walls could be designed similar to enclosed walkways presently used to connect buildings over busy streets in cities. Routing at grade and under highways would also help alleviate distasteful appearances. In addition, reduced pressures would allow smaller tubes to be used and these tubes would have greater routing flexibility. The use of maglev suspension would also further reduce vehicle maintenance costs. All-in-all, the combination of PRT with maglev is a good match.

A common concern with maglev for intra-city transit is the high magnetic drag at low velocities for EDS suspension. These problems could also be addressed by using control technologies that provide non-stop service to minimize low velocity travel and by incorporating magnets in rails at station locations. Non-stop service would also allow higher velocities to be effectively used and would improve system performance. Cruising velocities in excess of 100 mph (161 km/hr) would be practical within many cities due to 1) greater acceleration, 2) non-stop service, and 3) transit corridors of reduced pressure.

Finally, a PRT Maglev operating in tubes of reduced pressure would be practical for intracity and intercity service with the same system. PRT systems may not have previously be considered for routine inter-city service; however, reduced aerodynamic losses in low pressure tubes and dynamic formation of trains would alleviate disadvantages for this application. Intercity transit is perhaps the best application of PRT since it is during intercity transit that passengers spend hours awaiting the departure of jets or making connections. Proposed intercity service of SWISSMETRO (18, 19) would have transit times of 12 minutes between cities, innately eliminating advantages of larger train-size vehicles.

Figure 2 compares the guideway of a PRT maglev to that of SWISSMETRO and the Bechtel concept. For the PRT maglev, vehicular suspension structures are located in front of and behind the passenger cabin. A cost comparison is given in Table 1 (20).

TRANSIT IN TUNNELS AND AT REDUCED PRESSURES

Goddard (21, 22) first proposed transit (non-maglev) in evacuated tubes; however, it was not until the 1973 RAND study (23) detailed the synergism of maglev and low air resistance that high speed transit in evacuated tunnels became feasible. Development of these concepts continue with NASA's New Millenniums Concept (John Rather, NASA Headquarters) and with SwissMetro (18, 19, 24). Modifications to the base concept include using of gravity to store energy (25, 26) and extending the concept to personal rapid transit (PRT) (27, 20). The extension to PRT service can actually have a greater impact on transit time than higher velocities.

The 1973 RAND study led the course for maglev transit in evacuated tubes and identified all-encompassing technologies which were available in 1973. In fact, the greatest hurdle to implementation was identified as tunneling technology, or rather, tunneling costs.

Suppes (20, 27) directly addressed these tunneling costs by identifying methods for reducing tunnel diameters, reducing the number of necessary tunnels, and allowing above-ground tubes. Both reduced tunneling costs and at-grade routing were made possible by using smaller vehicles which could travel is smaller tubes. Figures 2 and 3 illustrate the vehicle and tube sizes for the PRT maglev. As detailed in Table 1, these PRT tubes would actually cost less than high speed train routes.

SWISSMETRO uses two tunnels connecting the stations (see Figure 2), and the tunneling costs represent about 75% of the capital costs. The PRT maglev could offer bidirectional service in one tunnel (see Figure 2). Eliminating one tunnel would reduce the SWISSMETRO cost by about 37.5%.

Initially proposed tunnel pressures for SWISSMETRO and the PRT maglev are similar to those surrounding supersonic aircraft at cruising altitudes, and similar to aircraft, the passenger compartments would be pressurized to maintain passenger comfort. By using pressures ranging from about 0.01 to 0.1 atm, SWISSMETRO would use smaller diameter tunnels to reduce capital costs while simultaneously reducing the energy consumed by the trains. Key advantages of SWISSMETRO to the Swiss public are reduced energy consumption and reduced environmental impacts due to smaller tunnels.

Upon first consideration, the concept of travel in low pressure environments can be rather distressful; however, low pressure travel environments are routinely used by passenger aircraft. While on earth's surface our body is accustomed to pressure of 1 atm (101 kPa), at typical passenger jet cruising altitude of 30,000-40,000 ft (9000-12000 m), the pressure ranges from 0.30-0.20 atm (30-20 kPa). In aircraft, scoops and compressors gather air to maintain pressure in the passenger cabin. Similar methods would be used for SWISSMETRO and the PRT maglev. It would be prudent to design initial PRT Maglevs to operate at the lower pressures (0.2 atm) presently used by commercial aircraft so as to minimize initial development needs. Optimal pressures for low pressure applications would depend on travel velocity and would vary from approximately 0.2 atm (20 kPa) to approximately 0.001 atm (0.1 kPa).

ENERGY CONSUMPTION

Aerodynamic Drag

The upper curve of Figure 4 estimates (does not account for trans-sonic and super-sonic variations in drag) a constant aerodynamic drag and shows how pressure can be reduced to compensate for otherwise increased drag at higher velocities. Optimal pressures depend upon many factors including the dynamic use of train units, the use of aerodynamic designs, tube diameters, and technology on propulsion systems. The walls of the tube would increase drag, and for purposes of this paper the walls are assumed to double the aerodynamic drag. To streamline the PRT Maglev trains, the lower vehicle design of Figure 3 would be preferred.

To calculate the drag (R_c) of a train of length L and perimeter P_c, A.I. Totten (28) has proposed Equation 1:

$$R_c = \left[0.0020 \; P_c \left(\frac{L}{100}\right)^{0.8} + K \right] V_x^2 \quad (1)$$

Equation 1 accounts for formation of train units. Wall effects were incorporated into equation 1 by multiplying Ra by a factor of 2 and air density is taken into account by multiplying by a further factor equal to the tunnel pressure in atmospheres pressure.

To minimize systematic errors, calculations using equation 1 were made relative to the Bechtel concept. The perimeter of a train is assumed to be approximately 2.7 times greater than that of the PRT Maglev, and the length of the PRT Maglev train is a factor of two greater due to only having three passengers seated across rather than six (only five are pictured; however, the Bechtel concept proposes six seats across) as with the Bechtel concept. Another 50% increase in length is added to accommodate improved comfort and PRT vehicle constraints. In total, a PRT Maglev train would have an average length approximately three times greater than a train accommodating the same number of passengers.

Based on this analysis summarized in Table 2 , at 300 mph (482 km/hr) and 0.2 atm (20 kPa) of pressure, the PRT Maglev would have 63% less aerodynamic drag than a 300 mph (482 km/hr) train operated at atmospheric pressure. Using similar calculations at 500 mph (805) and 0.05 atm (5 kPa), the PRT Maglev would consume 75% less energy than to train to overcome aerodynamic drag. To reduce greenhouse gas emissions, combinations of low pressure and velocity could be used to reduce energy consumption to 50%, 20%, 10% . . . of the energy consumed by the best available alternatives.

Magnetic Drag

For electrodynamic suspension, magnetic drag losses are proportional to the weight of the vehicle and are inversely proportional to travel velocity. The generally accepted form of the drag equation is given by equations 2 and 3 for high velocities. Here Fy is the vehicle weight, n is the total number of coils in magnets, I is the current in each coil, h is the height of levitation, t is the thickness of the conductive track, and s is the conductivity of the track.

$$F_y \propto \frac{nI^2}{h} \quad (2)$$

$$F_x \propto \frac{-1}{k\,t\,v_x} \quad F_y \propto \frac{-nI^2}{k\,t\,h\,v_x} \quad (3)$$

where

F_y = vehicle weight
n = total no. of coils in magnets
I = current in each coil
h = height of levitation
t = thickness of conductive track, and
k = conductivity of track

For the Bechtel 64 Mg maglev train traveling at a velocity of 300 mph (483 km/hr), the magnetic drag energy consumption is estimated at 0.64 MW while the aerodynamic drag energy consumption is estimated at 5.4 MW. Aerodynamic drag dominates the energy consumption for both the Bechtel concept and the present PRT Maglev concept operating at 0.2 atm (20 kPa). At 500 mph (805 km/hr) and approximately 0.03 atm (3 kPa), magnetic and aerodynamic drag would be approximately equal, and at less than 500 mph (805 km/hr) and 0.01 atm (1 kPa) the presence of magnetic drag significantly diminishes advantages of lower tube pressures.

Analysis such as this can be used to define feasible pressure versus velocity profiles such as that shaded in Figure 4. Figure 4 is specific to the PRT Maglev. Larger vehicles, lower magnetic drags, and different vehicle-tube clearances would change the window of opportunity.

System Evacuation

Comparison to Train Systems

Energy consumption for tube evacuation would originate from the three needs of 1) periodic "total" tube evacuation, 2) evacuation associated with vehicle/passenger entry and departure, and 3) air leaks of the tube system. Of these, further information is needed to evaluate the impact of air leaks. In practice the cost of leaks would justify use and development of advanced leak detection methods and coatings which would bring leaks under control.

The cost of total tube evacuation would be incurred periodically when the tube is exposed to atmospheric pressure for maintenance or for emergency procedures (e.g., emergency evacuation by flooding the tubes with air and having passengers walk to a tube exit). Standard adiabatic compression calculations were used to estimate the compression energy. Compression was modeled as a dynamic process with tube pressure decreasing as evacuation progressed.

For four tube evacuations per year, a compression efficiency of 80%, and a tube length of 800 km; 3.6, 5.6, 8.4, and 9.2 million MJ are required to remove 16 Gg of air and produce a pressure of 0.2, 0.1, 0.01, and 0.001 atm respectively. As listed in Table 3, this translates to 360-920 J per passenger mile or < $0.00002 per passenger mile. A similar calculation for the evacuation of the volume of a vehicle exterior for entry of a vehicle into the tube equates to < $0.0001 per passenger mile.

While periodic tube evacuations and vehicle entries have evacuation costs which level out at lower pressures, compression costs associated with continuous removal of air (from leaks) increase rapidly with lower internal pressures. At pressures less than 0.02 atm (2 kPa), these compression costs could become significant. Insufficient data is available to make estimates on these costs.

Comparison with Air Travel

In addition to comparing evacuation costs of the PRT Maglev to train system costs, these evacuation costs should also be compared to corresponding costs for air travel. For air travel, energy is expended to overcome earths gravity to achieve higher altitudes where lower pressures are available. At a mass of 500 kg per seat and a cruising altitude of 12,200 m (40,000 ft), 59.8 MJ of energy are consumed in overcoming gravitational forces. This compares to approximately 2.5 MJ of evacuation energy per passenger. Considering other factors such as energy for aircraft takeoff and the initial and final travel at atmospheric pressure by the aircraft, over forty times more energy is consumed to transport a passenger to low pressures by an aircraft than would be needed to maintain/enter low pressures in PRT Maglev tubes on earths surface for travel.

DISCUSSION OF RESULTS

System Costs

The cost estimates of Table 1 include both capital and energy consumption costs. A basis of 10 million roundtrips per year (3,500 passengers per hour per direction for eight hours per day for 365 days in a year) was used to allow capital and energy consumption costs to be compared.

Energy consumption is based on Bechtel's (12) oneway trip energy consumption of 19,000 kWh for a 497 mile (800 km) trip. (The 19,000 kWh is from Table A-3 of reference 12 and is based on the total trip and not just cruising velocities.) At 60% occupancy, 120 seats per vehicle, and $0.08 per kWh; the electrical energy costs $42.2 per passenger roundtrip or $0.85 million per year per mile of bidirectional track. As detailed in Table 2 , the 0.2 atm 300 mph PRT maglev has about 37% of the aerodynamic drag of Bechtel's concept or about $0.38 million per year per mile of bidirectional track with similar magnetic drags. These costs as well as vacuum and magnetic drag costs are also summarized by Table 3.

Capital costs are based on a direct comparison to Bechtel's reduced first cost estimate (12) which uses a higher cost for electrical power ($0.08 per kWh versus $0.055) with the advantage that local electrical companies would construct and manage guideway electrification facilities. Cost reductions in the PRT maglev capital reside in 1) reduced structure costs, 2) reduced propulsion costs, 3) reduced costs for stations and parking, and 4) reduced vehicle costs.

A 40% reduction in structure costs is based on a less expensive combined structure illustrated by Figure 2 . A further 25% reduction (12) is based on at-grade construction which is feasible due to a smaller cross section of the PRT maglev route.

Reduce propulsion system costs are claimed due to a 55% reduction in the combined aerodynamic and magnet drag of the PRT maglev as well as the use of a train unit which is three times longer for the PRT maglev. In total, the cruising propulsion requirements of the PRT maglev are only 15% of those of Bechtel's concept on a thrust per length of guideway basis.

Reduced station costs are associated with the smaller size of stations and incorporation with local metro service. Reduced vehicle costs are based on RIM production methods and shorter transit times leading to a need for fewer seats.

As a final comparison of costs and energy consumption, Table 3 compares the present calculations to those calculated in the analysis of a Canadian maglev system (1) as well as the Bechtel concept. The largest contribution to transit costs with maglev trains is the interest on capital and the second largest expense is that for electrical power. Costs to produce a tube pressure of 0.2 atm are negligible. A cost estimate including interest and energy costs amounts to a mere $0.059 per mile of travel.

The advantages of train systems in comparison to air travel can be readily seen. The savings in energy between the 300 mph, 0.2 atm PRT Maglev (483 km/hr, 20 kPa) and a B757 translate to about 264 Wh/seat-km or about $0.013 per mile of track at an energy cost of $0.03/kWh.

Comparison of Performance with Air Travel

An initial PRT Maglev system operating at 300 mph and 0.2 atm (483 km/hr and 20 kPa) would be faster and more convenient than any other land based transportation system; however, air travel would have advantages at greater distances. To calculate the point at which air travel would have reduced transit times as compared to the PRT Maglev, certain assumptions must be made on the transit to airports, wait before departure, layovers, and wait after arrival. Table 4 lists the assumptions used for a comparative analysis. The source of the data includes published sources (29), airlines (recommendations on when to arrive at airport before departure), and personal experience.

The basic difference between the two air transit scenarios is that Air 1 is a direct flight and Air 2 includes a layover. The basic difference between the PRT Maglev scenarios is that PRT A operates at a maximum velocity of 300 mph (483 km/hr) and PRT B operates at a maximum velocity of 500 mph (805 km/hr). Both PRT Maglev systems assume access from several locations within both cities and therefore have the average 10 minute transit time to the station.

As illustrated by the data of Table 4, a PRT Maglev with a maximum velocity of 300 mph (483 km/hr) would have shorter transit times than air travel at distances less than 907 miles (1460 km). With a maximum travel velocity of 450 mph (724 km/hr), the PRT Maglev would have shorter travel times for all travel within the continental United States. Based on these results, initial PRT Maglev systems having a maximum travel velocity of 300 mph would be the best available alternative for destinations up to 907 miles distant. A later increase in velocity to 500 mph lead to service better than any alternative in the continental United States.

Transportation Network

The PRT Maglev system could become a transportation network similar to our present highway system based on our interstate highway network. Local metro PRT Maglev tubes would be connected to interstate tubes, and each section would have a speed limit (speed set-point) for normal operation. Propulsion power would be supplied by linear motors along the tracks. Auxiliary propulsion from the vehicle would allow deviation from the speed set-point to allow the dynamic formation of trains to accommodate entering and exiting traffic. As high temperature superconductivity becomes reality, electric powered cars could be manufactured with magnetic suspension systems located within the four quarter-panels and, similar to HOV lanes, wheeled vehicles could literally drive onto and into a maglev transit corridor where automated maglev suspension would take over for much of the trip.

Local metro service could provide much needed pollution-free service to our cities. For cities, typical maximum upper speed set-points would initially be approximately 100 mph (161 km/hr). Depending upon the distance of travel, service could be in low pressure tubes or open to the atmosphere. The interstate network would be connected to local metro lines, and for the interstate network initial upper speed set-points would be approximately 300 mph (483 km/hr) with later speed set-points up to 3,000 mph (4,830 km/hr).

The combined network of local, intercity, and even transcontinental routes would provide

PRT service from a location close to travel origination to a location close to the final destination, and travel in low pressure environments makes very fast travel possible and minimizes environmental impact. Service would readily evolve to operation similar to an elevators where no advanced reservation is necessary and where railway stations are replaced with elevator entrances at multiple locations within cities. The high energy efficiency, low maintenance (due to very few moving parts and isolation from environment), and comparatively low capital costs would allow PRT Maglevs to cost less other modes of transportation. Lastly, reliance on electrical power allows ecological impact and cost to improve with new technology on electrical power generation.

Areas for Advancement

The PRT Maglev concept is new, and as such, many opportunities exist to improve.

One important area already emphasized is associated with operation at reduced pressures. It would be advantageous to operate initial systems at 0.2 atm (20 kPa) since this is an established standard for commercial aircraft, equipment is available, and the public has already accepted transit with vehicle exteriors at these pressures. Advancing to travel at increasingly low pressures leads to increased velocities, reduced energy consumption, and reduced travel times.

Improved tunneling, structures, and routing methods could reduce costs by reducing the guideway structural costs. Much could be gained from a concentrated research and development effort in this area.

Additional advantages could be realized by reducing the vehicle weight. Weight reductions should be able to match the specific weights for an automobile (300 kg per seat). Reduced vehicle weight leads to reduced forces on guideways and reduced magnetic drag.

An additional area for advancement would be the incorporation of superconducting rails for repulsive levitation. The NMI study (12) lists magnetic drag as ranging from 6 to 40 kW/ton for conventional conductors. Superconducting rails would reduce these values many fold and allow lower pressures to be used to reduce energy consumption costs to approximately one dollar for a 1600 km roundtrip. Such advances would make parcel service (30) of all sized packages feasible with maglev. Automated transit during off-hours could ship such freight with minimal increased capital and significantly increased profits. Without superconducting rails, freight could be shipped at costs of approximately $0.000023 per kg per mile during off-peak (11:00 PM to 6:00 AM) hours at lower velocities of approximately 200 mph.

CONCLUSIONS

Compared to 300 mph (483 km/hr) maglev trains, a 300 mph, 0.2 atm (20 kPa) PRT

Maglev would require approximately 56% of the infrastructure cost at $10 million per mile as compared to $17.9 million per mile of bi-directional guideway. The energy requirements of the 300 mph Maglev would be approximately 45% of that corresponding to a train system. Such a 300 mph, 0.2 atm PRT Maglev would operate at low pressures typically encountered by commercial aircraft and no new developments or breakthroughs would be needed for maintaining cabin pressure.

A similar PRT Maglev system at 500 mph (805 km/hr) would offer a 25% reduction in travel time due to higher velocities and even further time reductions due to PRT service. However, a 500 mph, 0.2 atm PRT Maglev would consume a similar amount of energy as the 300 mph Bechtel concept and would have similar system costs. On option for alleviating the higher costs at 500 mph is to reduce internal tube pressures to between 0.03 atm and 0.1 atm (3-10 kPa). Both increasing velocities to 500 mph and decreasing pressures to 0.05 atm could be performed as evolutions to an initial system operated at 300 mph and 0.2 atm.

The proposed PRT maglev is similar to SWISSMETRO which is currently being developed in Europe; however, the PRT maglev would require 37.5% less capital in the form of tunneling costs. In addition, many US routes would have preferred routing at-grade rather than in underground tunnels. At-grade routing would reduce costs but may limit travel velocities. For the present purposes, acceleration and comfort considerations were defaulted to be those used by the NMI studies (12).

Based on the results of this preliminary study, a PRT maglev designed with a cruising velocity of 300 mph in tubes at 0.2 atm would be faster than present alternatives up to distances of 907 miles (1460 km). In addition, the energy to maintain tube vacuum is greater than forty times less than the energy needed to attain altitudes of similar low pressure. This PRT maglev would be able to evolve such that lower tube pressures and increased velocities would allow the PRT Maglev to have reduced travel times for all travel routes viable with surface routing. A mature system would include velocities up to 3,000 mph (4,830 km/hr) and connections between Asia and America.

Long Beach-Hinson 220KV Transmission Line Right of Way
South of Willow Street, City of Long Beach
Contract Nos. 9000000002241 and 9000000001472

Dear Mr. White,

Thank you for meeting with Christine Fanous and me on Thursday, November 3, 2011 and for your letter providing a conceptual outline for a proposed reduced footprint along with pertinent information about Three Rivers Trucking ("Three Rivers"), a description of your current operations, and your inquiry to find a future solution to Three Rivers operations which appear to be impacted by the Burlington Northern Santa Fe ("BNSF") Southern California International Gateway (SCIG) proposed yard tracks within the Southern California Edison ("SCE") Transmission Line Right of Way located south of Willow Street, in the City of Long Beach.

As you may know, SCE has received a request from BNSF to relocate existing SCE facilities and for the acquisition of an easement to accommodate the BNSF SCIG yard tracks within the SCE Right of Way. The SCIG conceptual design showing the approximate track footprint within the SCE Right of Way indicates that the BNSF project appears to impact the dock, office, and maintenance buildings.

As we discussed, SCE reviewed your request for SCE to relocate the impacted buildings at other locations within the SCE Right of Way. SCE's Land Use Policy however only allows for low intensity uses on our Right of Way and does not allow permanent structures. Therefore, you were informed that SCE must deny your proposal for SCE to replace the impacted existing building by constructing new buildings at other locations within the SCE Right of Way.

As we also discussed, SCE may consider allowing Three Rivers to license the remaining SCE Right of Way, after the proposed easement acquisition for the BNSF project, for parking purposes only, but no structures.

If you have any questions regarding the above, please email me at Roslyn.Delmar@sce.com or call me at (626) 302-4120.

Sincerely,

Roslyn Delmar

ROSLYN DELMAR
Right of Way Agent

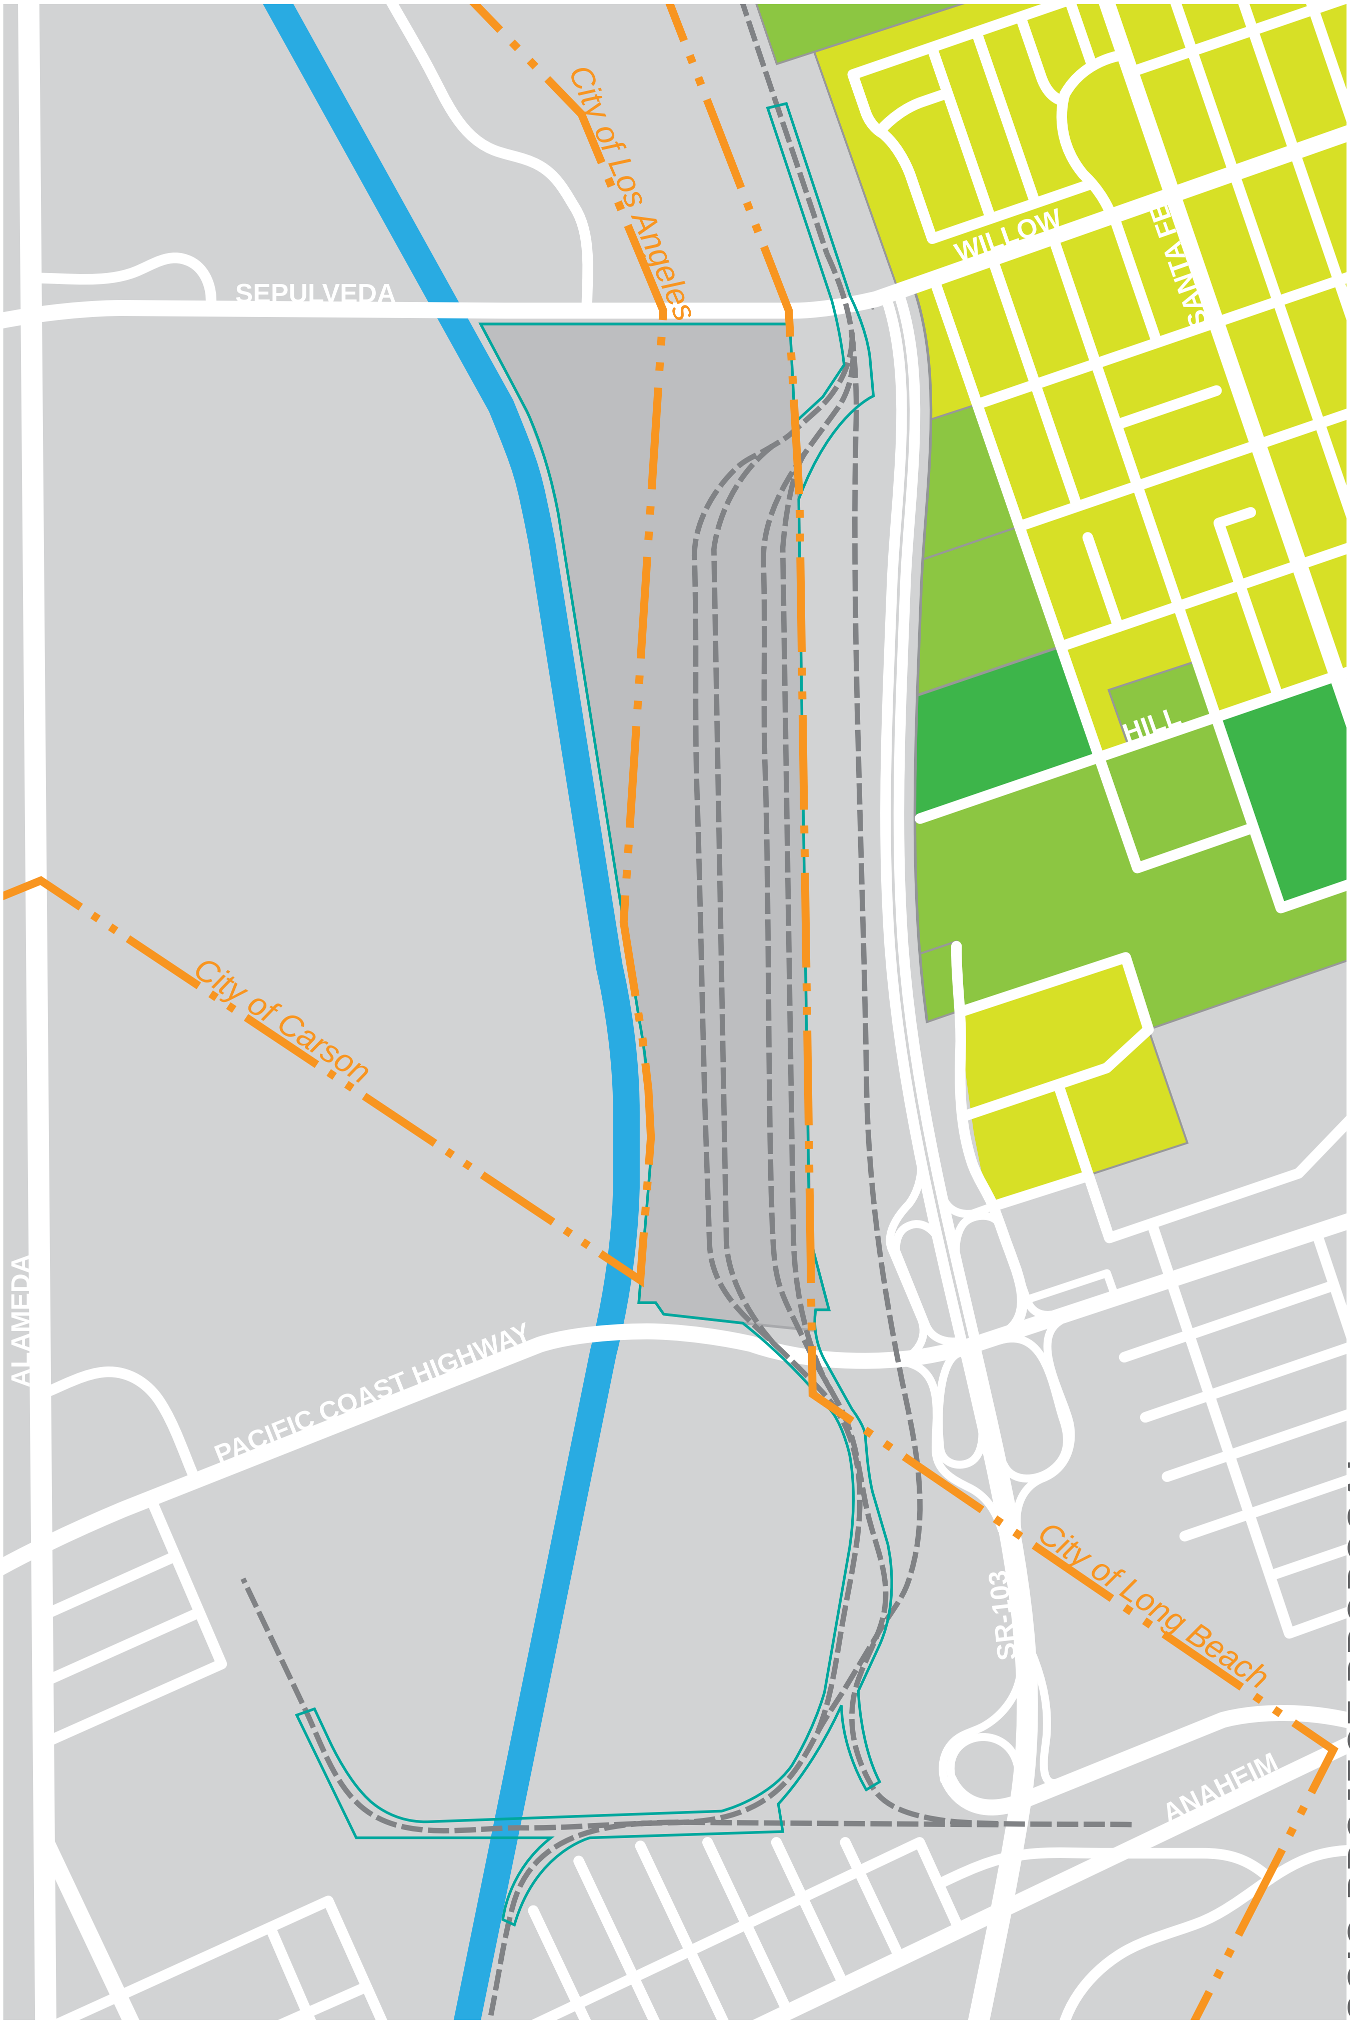
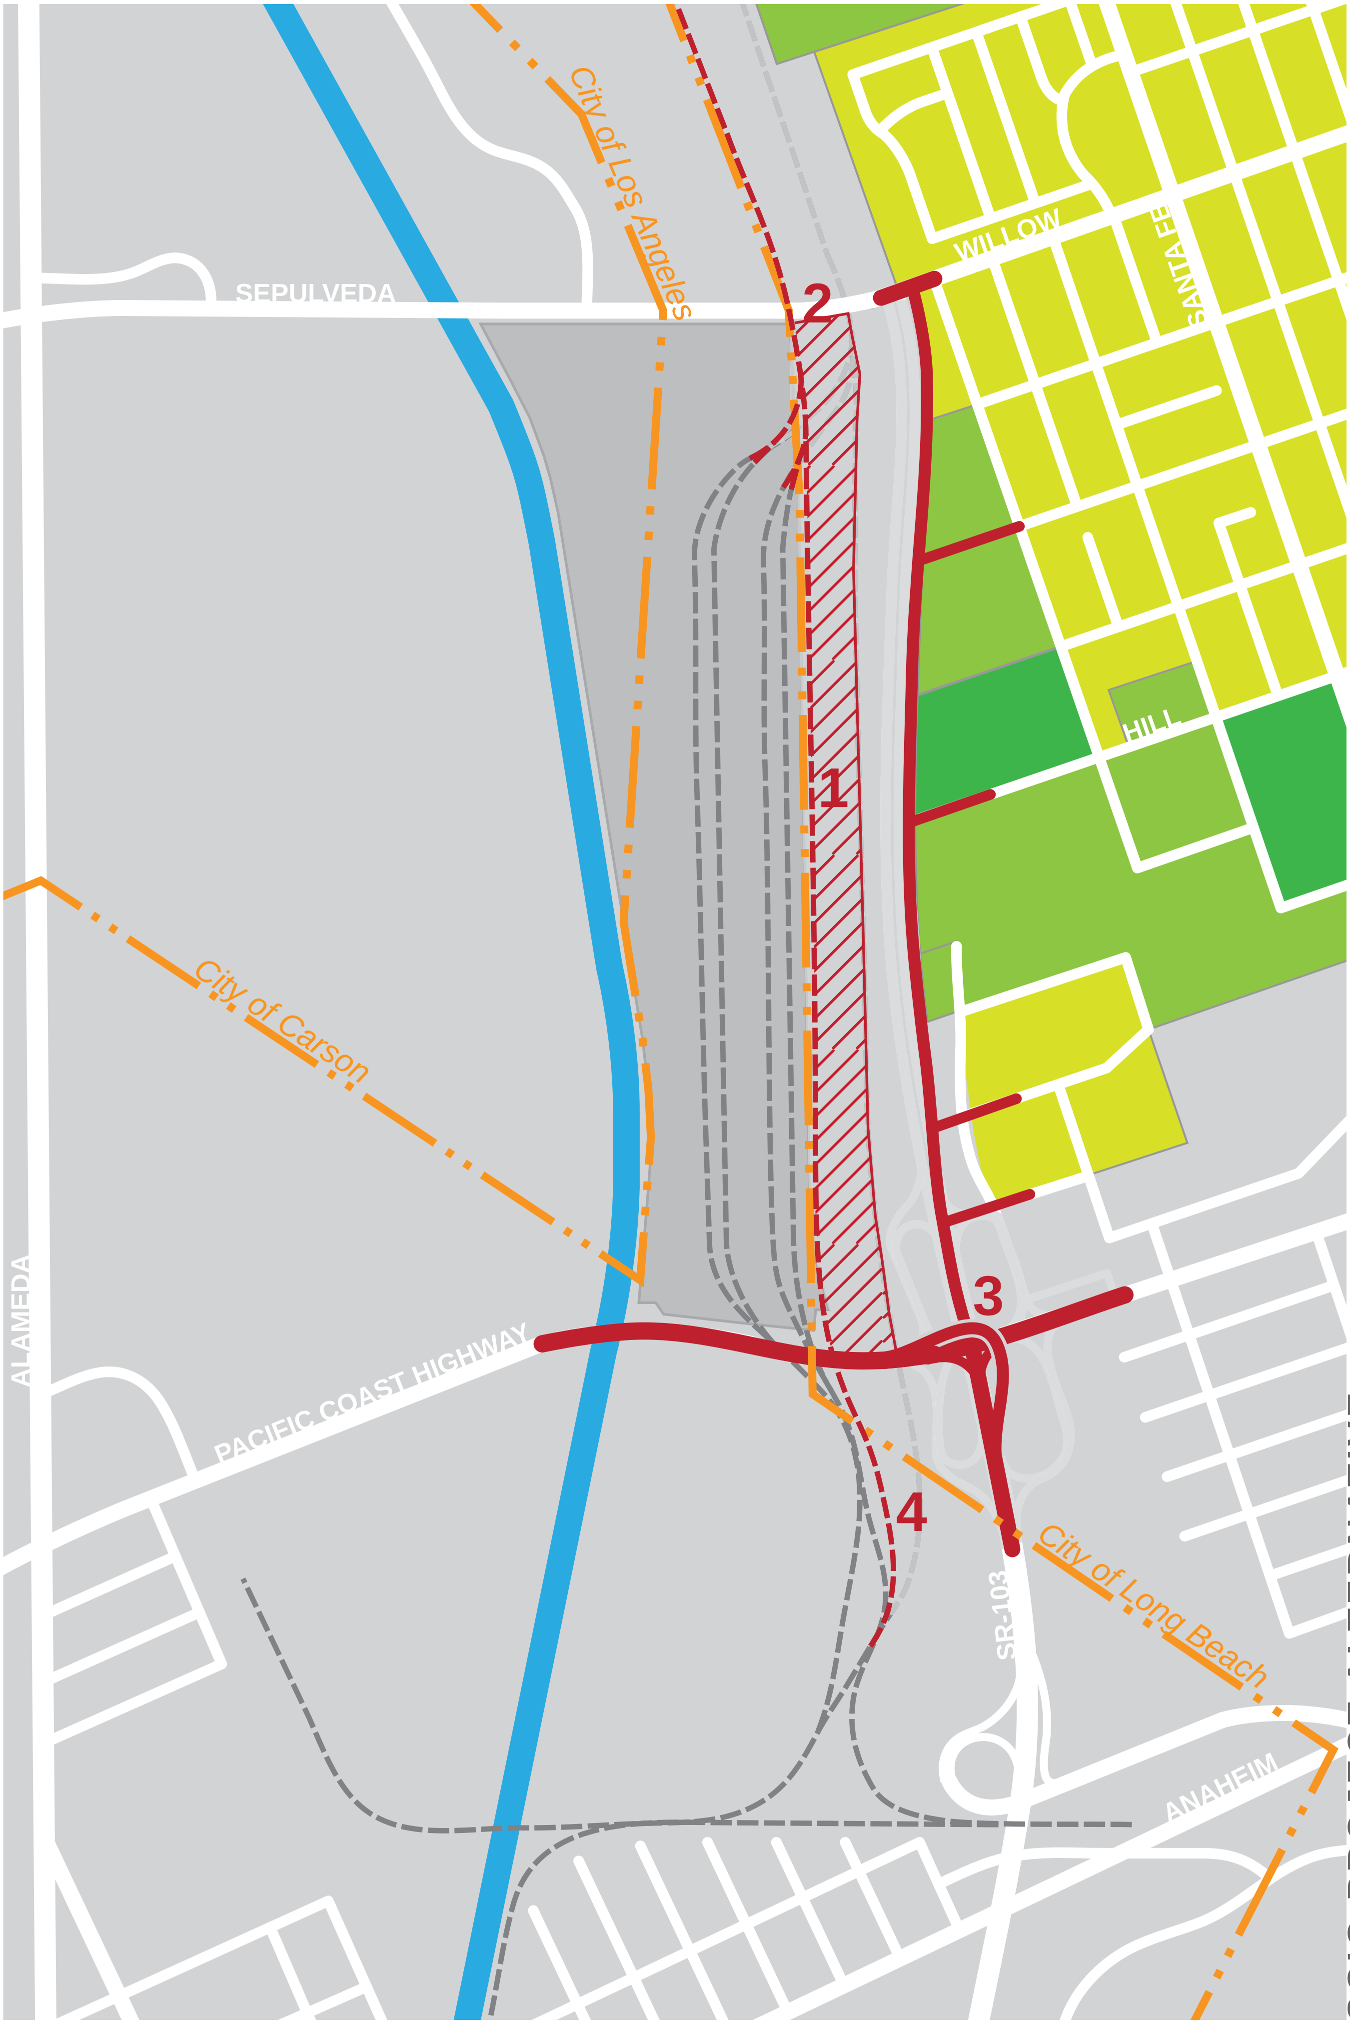
SCIG-DEIR PROJECT MAP



SCIG PROJECT PROPOSAL



SCIG PROJECT ALTERNATIVE

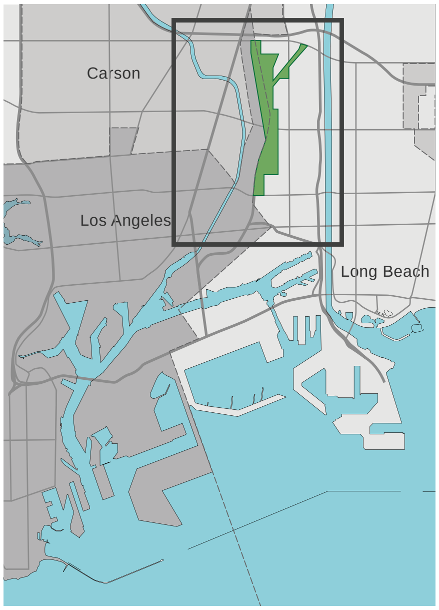
THE YARDS: open space proposal

REGIONAL PARK Create a regional-scale park to serve the Westside and other surrounding communities.

ENVIRONMENTAL BALANCE Provide a carbon sink to mitigate port related air pollution while reducing urban heat island effect.

LAND-USE SEPARATION Establish a greenbelt that physically separates the residential population from freight infrastructure.

IMPROVE LOCAL CONNECTIVITY Improve local infrastructure serving goods movement and residential community.



Vicinity Map

Cornfields State Park in Los Angeles (former railyard)

Why Here?

LAND OF OPPORTUNITY
Long Beach is one of the densest cities in the nation with few opportunities to create new parks for communities most lacking. Because of land-use patterns, West Long Beach has perhaps the best prospects for developing a new park of substantial size.

LIMITED PARK SPACE
West Long Beach is woefully underserved by open space. There is less than one acre of public parks per 1,000 residents where the Eastside of Long Beach has over 16 acres per 1,000 residents including four of the city's largest parks.

ENVIRONMENTAL JUSTICE
West Long Beach is completely surrounded by the port, refineries, industry and freeway infrastructure impacting resident's quality of life. In most cases there is little physical separation from the predominantly low-income, minority neighborhood.

Why Now?

NEW CONSTRUCTION
Hundreds of acres of land and dozens of miles of train tracks will be redeveloped as part of three new and modernized rail facilities. Instead of moving existing facilities there is a unique opportunity to plan them holistically to benefit everyone.

INFRASTRUCTURE REALIGNMENT
New infrastructure projects around West Long Beach will result in more efficiency and greater capacity for goods movement from the port. Many of these projects would actually create the opportunity to repurpose redundant infrastructure for public use.

ENVIRONMENTAL MITIGATION
There are currently seven major infrastructure projects proposed in and around West Long Beach. While environmental mitigations are proposed for these projects they could achieve more as part of a larger vision for benefiting the community.

Questions?

Contact Brian Ulaszewski bulaszewski@hotmail.com 323.309.7932

THE YARDS open space proposal

CONSOLIDATE PORT-SERVING INFRASTRUCTURE

Shift port support facilities and infrastructure (existing and/or proposed) to the west, adjacent to the Dominguez Channel and the Alameda Corridor. Realign San Pedro Railroad Branch west to more efficiently serve port support facilities.

RECONFIGURE CITY-OWNED TERMINAL ISLAND FREEWAY WITH SAN GABRIEL AVENUE

The City of Long Beach owned portion of the Terminal Island Freeway north of Pacific Coast Highway carries fewer vehicles than Fourth Street (one travel lane in either direction, with a left turn lanes). Replacing the last one-mile length of the freeway with a neighborhood scale street can improve local circulation while shifting truck traffic to the Alameda Corridor.

REPURPOSE SOUTHERN CALIFORNIA EDISON RIGHT-OF-WAY

A large portion of the Southern California Edison (SCE) transmission corridor on the Westside is currently vacant of accessory uses. While retaining necessary access and security for electrical transmission facilities, enter into lease our purchase agreement for public use of the ground plain.

SHARE LONG BEACH UNIFIED SCHOOL DISTRICT RECREATION FACILITIES

Four Long Beach Unified School District (LBUSD) campuses abut the western edge of city boundaries and port supporting infrastructure. Establish reciprocal joint-use agreements for the recreational facilities adjacent to the SCE transmission corridor.

DEVELOP REGIONAL SCALE PARK IN WEST LONG BEACH

Combine vacant parcels, under-utilized right-of-ways to create the second largest park in Long Beach along the western edge of the City.

Kirk is the Founder of CEA and has been at the helm as a Principal since 1984. His deep experience in energy and environmental regulation provides the foundation for CEA's work with a variety of private and public sector clients. Prior to establishing CEA in 1984, Kirk was the Under Secretary of California's Natural Resources Agency and served as the Director of the Office of Appropriate Technology. He also held various positions at the U.S. Department of the Interior. At California's Natural Resources Agency, Kirk was responsible for managing budget and policy initiatives of the agency's nine departments. He resolved policy conflicts among departments, cabinet officers, legislators, companies, and private citizens. Later, he worked as a consultant with the Environmental Defense Fund to help implement programs in energy, water, and hazardous materials.

Kirk has led large-scale regulatory reform and strategic planning projects for major manufacturing and transportation companies as well as for trade associations and nonprofits. He has represented individual clients and trade associations before legislative and regulatory agencies in California and Washington, D.C. In July 1999, Governor Davis appointed Kirk as a public member of the California Board of Forestry, where he served as the Vice-Chair of the Board until 2007. Kirk currently serves as the Chairman of the Board of the Institute for Local Self-Reliance and on the Boards of the Pacific Forest Trust, the Blue Mountain Center and the Point Reyes National Seashore Association.

Kirk has a master's degree in Natural Resources Policy and Management from the University of Michigan and a bachelor's degree from Trinity College.

ZECMS	Zero Emission Container Movement System

1. Introduction

For the last five years, the ports of Long Beach and Los Angeles have been evaluating zero emission goods movement technologies prompted by Boards of Harbor Commissioners that are keenly interested in leading the nation's two greenest ports into a cleaner future, by community demands for cleaner air, and by regulatory pressure to reduce the ports' "fair share" of air emissions. The purpose of this report is to provide a roadmap for moving forward with the identification, evaluation, and integration of zero emission technologies into ongoing port-related goods movement.

This report was jointly prepared by the staffs of the Port of Long Beach and Port of Los Angeles, with assistance from Starcrest Consulting Group, LLC. This report will:

- Define and clarify what is meant by "zero emission technologies" and how employing such technologies in the appropriate manner can assist the ports and the region in meeting their air quality and health risk reduction needs;
- Describe the technical and programmatic attributes of candidate zero emission technologies, including how they can be potentially integrated into goods movement;
- Explain the criteria and the process used to uniformly and impartially evaluate the technical and programmatic viability of zero emission technologies for drayage over short-haul distances and for in-terminal container handling equipment, and that will also be used for evaluation of additional technologies and other source categories in the future;
- Present the findings of the evaluation process for zero emission technologies, including constraints and opportunities related to near-term and longer-term options;
- Present recommendations for "next steps" in implementing zero emission technologies into port-related goods movement operations.

By the end of this paper, the reader should have a clear understanding of the roadmap for moving forward with zero emission technologies in port-related operations, based on the following key principles:

- The ports should pursue zero emission technologies for those segments of port operations where technically feasible and economically viable solutions are most likely to develop - on-road drayage, in-terminal container handling, and railroad locomotives.
- The ports must identify the technology options that are best suited for integration into port-related operations (e.g., duty cycle).

- The ports must preserve flexibility in their approach to allow future zero emission technology advancements to be integrated into port-related operations.
- The ports must consider the ability of any proposed zero emission strategy to scale out to the region in order to maximize port-related and regional air quality and health risk reductions.
- None of the zero emission technology options considered to date is ready for full-scale implementation. However, the ports will immediately move forward with demonstrations and collaborative efforts that advance promising technologies toward feasible real-world implementation.

Further, the ports must consider that, when evaluating the potential benefits and costs of the various zero emission technology options, resources will also be needed to help develop and implement control strategies for ocean-going vessels (OGVs) and harbor craft in order to achieve the San Pedro Bay Standards.

1.1. What are Zero Emission Technologies?

"Zero emission technologies" have been defined by the California Air Resources Board (CARB) as technologies that do not directly emit criteria pollutants, such as hydrocarbons, carbon monoxide, nitrogen oxides (NOx) or particulate matter (PM). Zero emission technologies may indirectly produce small amounts of emissions, for example, when an electric vehicle plugs into grid power to recharge the on-board batteries, therefore contributing in small part to emissions at the power plant source.

Since 2006, the ports have been evaluating opportunities for Zero Emission Container Movement Systems, or ZECMS, to move cargo through the ports and into the region using technologies that do not burn fossil fuels and therefore do not emit air pollutants "at the tailpipe".

The ZECMS title however gives the impression that there will be a "one-size-fits-all" zero emission option that will apply in all port-related operations. As will be discussed more fully below, such a concept is misleading and limiting, and does not fully address the needs of the various mobile sources involved in port-related operations. Accordingly, for the purposes of this paper and moving forward, with the exception of references to past activities, these technologies will be referred to by the more general and appropriate terminology of "zero emission technologies".

1.2. The Need for Zero Emission Technologies

The economic benefits of port-related activity are felt throughout the nation. However, the fact that the environmental impacts of trade are disproportionally felt in the local region led to the joint ports' landmark environmental initiative, the 2006 Clean Air Action Plan (CAAP). In the 2010 CAAP Update, the ports underscored their commitment to air quality improvement with the adoption of the San Pedro Bay Standards, which are comprised of two components: 1) reduction in health risk from port-related diesel particulate matter (DPM) emissions in residential areas surrounding the ports, and 2) "fair share" reduction of port-related air emissions to assist the region in achieving federal air quality standards. These components reflect the ports' stated goals of reducing health risks to local communities from port-related sources and reducing emissions to support the attainment of health-based ambient air quality standards on a regional level.

Specifically, the ports' Health Risk Reduction Standard is to reduce the population-weighted cancer risk of ports-related DPM emissions by 85% by 2020, relative to 2005 conditions, in highly impacted communities located near port sources and throughout the residential areas in the port region. The Emission Reduction Standards, relative to 2005 conditions are, by 2014, to reduce emissions by 22% for NOx, 93% for sulfur oxides (SOx), and 72% for DPM, and, by 2023, to reduce emissions by 59% for NOx, 93% for SOx and 77% for DPM.

While the ports have already made significant progress toward meeting these goals, as reflected in each port's annual emissions inventories, emissions forecasting indicate that the currently known emission reduction strategies will not be adequate to achieve the aggressive goals of the San Pedro Bay Standards. As a result, the ports must stay focused on identifying and reducing sources of port-related emissions. Staff believes that implementation of zero emission technology options could provide significant benefits to the ports, bringing them closer to achieving these goals, and in turn, assist the region in meeting national attainment standards.

Further, the South Coast Air Quality Management District (AQMD) has stated that in order to achieve the proposed federal ozone standards, the majority of land-based mobile sources will need to utilize zero emission technologies. The proposed U.S. Environmental Protection Agency (EPA) revised standards would reduce the 8-hour primary standard for ozone to a level between 0.070 and 0.060 parts per million (ppm), down from the 2008 standard of 0.075 ppm. The proposed rule also includes a separate cumulative "secondary" standard to protect the environment, especially plants and trees. If the proposed federal ozone standard is adopted, significant changes will be needed throughout all industries, as well as by private consumers, to meet these stringent air quality requirements for the region.

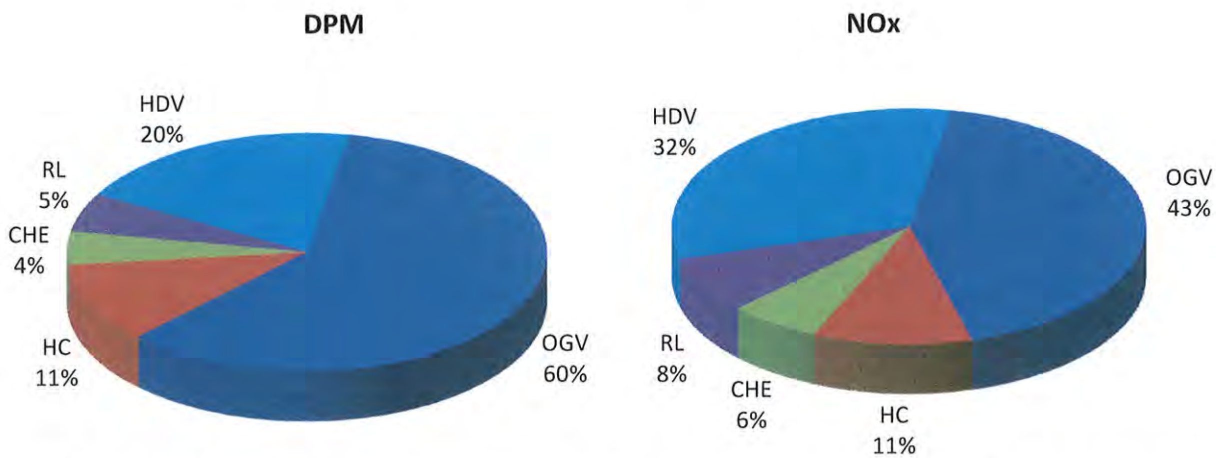
Additionally, utilization of zero emission technologies could be a significant strategy for reducing greenhouse gas (GHG) emissions. Each port, in cooperation with their respective City, has initiated a process to quantify, evaluate and implement strategies to reduce GHG emissions from their administrative operations as well as from port-related activities of their tenants and customers.

Finally, energy security (i.e., reducing dependence on foreign oil) is also a significant consideration as the ports transition into the future. Uncertainty about potential future supplies of oil and rising costs provide another reason for moving away from technologies that rely on fossil fuels to technologies that are powered by electricity ideally produced using renewable energy sources.

1.3. Potential Air Quality Benefits from Implementing Zero Emission Technologies at the Ports

The emissions source categories involved in port-related goods movement operations are OGVs, cargo handling equipment (CHE), drayage trucks (HDVs), rail locomotives (RL), and harbor craft (HC). Figure 1 is derived from each port's 2009 emission inventories and shows the relative contribution of emissions broken down by the source categories associated with such port-related sources.

Figure 1: 2009 DPM and NOx Emissions by Port Source Contribution



While the CAAP includes measures to mitigate air pollutant emissions from each of these major source categories, not all source categories are good candidates for transition to zero emission operation. For example, outside of at-berth operations (i.e., shorepower), it is not practical at this time to pursue zero emission operation of OGVs that call at the ports or harbor craft that operate within port waters due to technical and operational constraints.

The emissions standards being promulgated for OGVs and harbor craft by the regulatory agencies (International Maritime Organization, EPA, and CARB) do not require, nor even approach, zero emission levels. Secondly, and most importantly, zero emission technologies for commercial marine vessels do not currently exist and no practical zero emission technology solutions have been identified. While the goal of "zero emissions" is not appropriate for these source categories, technology options are being developed and implemented to mitigate emissions from OGVs and harbor craft, including the six OGV measures and one harbor craft measure included in the 2010 CAAP Update[1]. In fact, Foss Maritime operates the world's first hybrid-electric tugboat, demonstrating the opportunity for technology migration across applications. While not technically a zero emission tugboat, significant reductions in emissions and fuel consumption are being realized as a result of this advanced technology, which relies on earlier technology developments in the zero emission vehicle market.

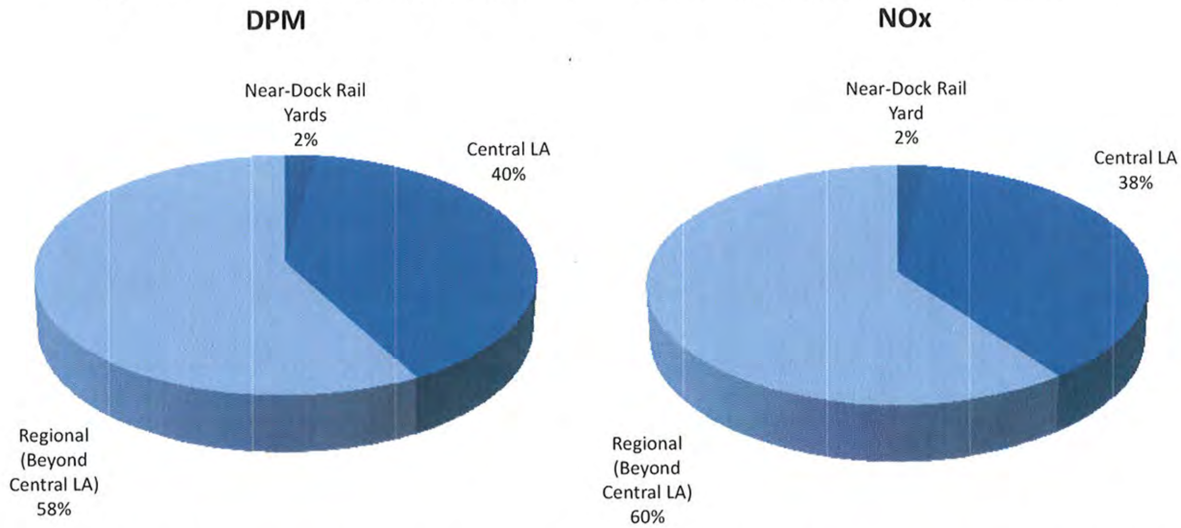
Additional emission reduction technologies for OGVs and harbor craft are being demonstrated under the ports' Technology Advancement Program (TAP). However, even with the successful implementation of these marine vessel emission reduction strategies, OGVs and harbor craft will remain the dominant source of port-generated emissions and the largest source contributor to community health risk for the foreseeable future. These two source categories represent 71% of total port DPM emissions and 54% of total port NOx emissions as documented in the 2009 emissions inventories. Therefore, while the ports must be diligent in their efforts to advance zero emission technologies, they must also be mindful that considerable resources will be needed to significantly reduce emissions from OGVs and harbor craft to achieve the San Pedro Bay Standards.

Technically feasible and economically viable zero emission options are most likely to develop for on-road container drayage conducted between the ports and destinations throughout the region, in-terminal container handling, and rail locomotives used in switching and line-haul operations.

In 2009, on-road drayage trucks produced 20% of total port-related DPM and 32% of total port-related NOx emissions. Of note, these percentages are anticipated to be reduced over the next few years with implementation of the Clean Trucks Programs at the ports. As shown in Figure 2, on-road drayage trucks emit the majority of their emissions during trips throughout the region. In 2009, *on-road truck emissions associated with the transport of cargo between port terminals and the Intermodal Container Transfer Facility (ICTF) represented 2% of total truck DPM emissions and 0.4% of total port DPM emissions.* On-road truck emissions associated with regional drayage represented 98% of total truck DPM emissions and 19% of total port DPM emissions in 2009. Therefore, while near-term efforts should move forward to develop technologies that can reduce emissions from on- and near-port drayage truck operations, ultimately, to provide the greatest benefits, zero emission technologies must be implemented on the regional scale.

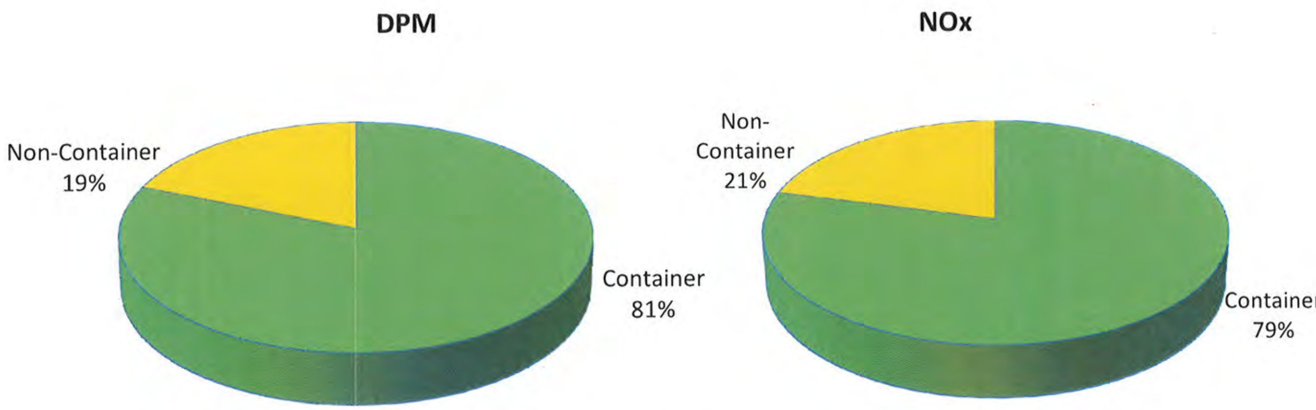
[1] 2010 CAAP Update includes the following OGV Measures: Vessel speed reduction (OGV1); At-berth emissions reductions (OGV 2); Low-sulfur fuels in OGV auxiliary engines and boilers (OGV 3) and in main engines (OGV4); Cleaner OGV Engines (OGV 5); and OGV Engine Emissions Reduction Technology Improvements (OGV 6). Harbor craft CAAP measure is HC1 – Performance Standards for Harbor Craft.

Figure 2: 2009 On-Road Drayage Truck DPM and NOx Emissions Contribution, by Mode



Cargo handling operations at marine terminals and intermodal facilities in close proximity to the ports generate 4% of total port-related DPM and 6% of total port-related NOx emissions. Figure 3 provides the breakdown of DPM and NOx emissions from CHE operations during 2009 at container versus non-container terminals. Since the majority of emissions from CHE are produced at container terminals, greater emissions benefits can be achieved by prioritizing implementation of zero emission technologies for CHE operations at container terminals.

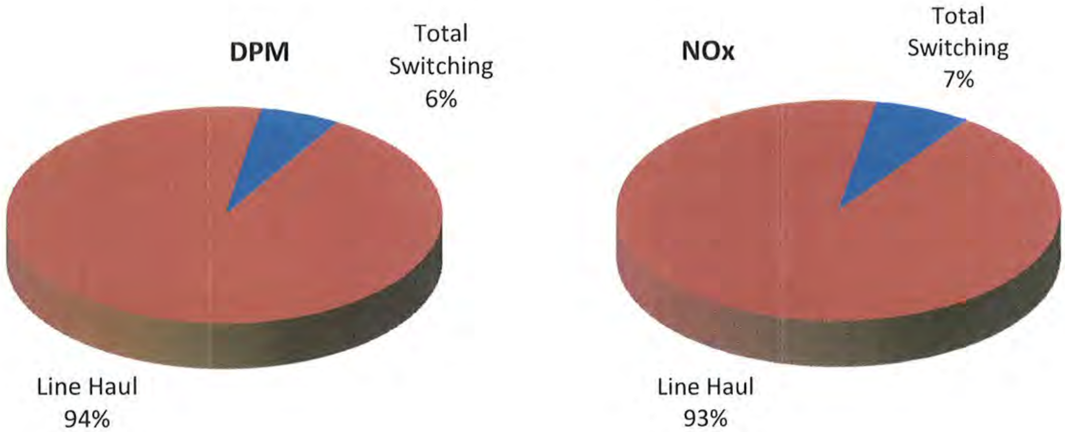
Figure 3: 2009 DPM and NOx Emissions Contribution from CHE by Terminal Type



Port-related rail operations generate 5% of total port DPM and 8% of total port NOx emissions. Rail locomotive emissions are primarily from line haul operations. As shown in Figure 4, 94% of DPM emissions and 93% of NOx emissions associated with port-related rail operations in 2009 were generated by the line-haul locomotives. Rail locomotive emissions are a regional source of air pollution;

thus, to maximize the emissions benefits, zero emission options targeting locomotive emissions should be pursued on a regional scale.

Figure 4: 2009 DPM and NOx Emissions Contribution by Rail Mode



The above analysis of port source emissions is the basis for seeking zero emission options for both port-scale and regional-scale goods movement. On the port scale, zero emission options will target emissions generated by short-haul container drayage and marine terminal operations. On the regional scale, zero emission options will target emission reductions from medium-haul drayage and rail.

Thus, for a zero emission technology to be an effective strategy in achieving the San Pedro Bay Standards, it must have scalability and connectivity throughout the region, and not applied only at discrete marine terminals or intermodal facilities within port boundaries. A zero emission option that connects only point "A" to point "B" within the ports, without the flexibility for expansion is not a viable zero emission solution for meeting the ports' goals.

1.4. The Ports' Role in Advancing Zero Emission Technologies

While the ports are principally interested in zero emission options to help them meet their health risk and "fair share" emission reduction commitments, the ports are also in a unique position to make additional, substantive contributions on a regional, national, and potentially global scale through developing, demonstrating, and supporting deployment of zero emission technologies.

Through the advancement of zero emission technology options, the ports are positioned to assume a lead role in the demonstration of zero emission transportation technologies and serve as a "regional test bed". Because port-related operations typically involve rigorous duty cycles, zero emission technologies that demonstrate the requisite levels of durability and reliability at the ports of Long Beach and Los Angeles can be replicated not only at other ports, but also in other non-marine applications.

Additionally, the pursuit of zero emission technologies provides an opportunity to serve as a "regional catalyst", stimulating both the pace of technology development as well as promoting economic development in Southern California. Currently, at least two zero emission vehicle manufacturers have established their businesses within the greater Los Angeles area, with the expressed intent of manufacturing zero emission on-road drayage trucks and off-road yard tractors for the port-related industry at commercial production rates. To ensure these technologies are carried beyond the ports, these efforts must be conducted with the support and collaboration of the regional planning agencies, including Metropolitan Transportation Authority (Metro), Southern California Association of Governments (SCAG), Gateway Cities Council of Governments, and AQMD.

2. Progress Toward Zero Emissions – Accomplishments to Date

Since 2006, the ports have advanced zero emission technologies through multiple pathways, investing over $4 million to date in this effort. The TAP has focused on numerous technologies, including zero emission options, which are ready for prototype demonstration in port-related applications. In addition, staff have also explored longer-term and larger-scale zero emission options through the ZECMS process.

2.1. Technology Demonstrations through the Ports' TAP

The mission statement for the ports' TAP is *"...to accelerate the verification or commercial availability of new, clean technologies, through evaluation and demonstration, to move towards an emissions-free port"*. The TAP is currently evaluating and demonstrating technologies that could eventually lead to deployment of zero emission technologies for sources in port-related operations. Some of those technologies represent interim or transitional technologies that help to significantly reduce air emissions, but are not yet emission free. Nonetheless, the deployment of these technologies in the near term will help the ports reduce air emissions and associated health risks while continuing to strive for full deployment of zero emission technologies in the appropriate areas of port-related goods movement for the future.

In 2007, the Port of Los Angeles and AQMD initiated a demonstration of the Balqon lead-acid battery electric truck. After initial testing, design upgrades were proposed for the battery management system, including an upgrade to a lithium-ion battery. In 2008, the Port of Los Angeles approved moving forward with phase 2, to purchase and test the upgraded systems for terminal applications, and phase 3, to purchase and test units made specifically for drayage. Phase 2 testing is currently underway. In addition, in an effort to further increase the range of the Balqon trucks, Port of Los Angeles is moving forward with combining the lithium-ion battery truck with Vision Motor Corporation's hydrogen fuel cell. Phase 3 of the system is anticipated to proceed in 3rd Quarter 2011. The tests for phases 2 and 3 will use upgraded lithium ion battery packs, which increase the energy capacity of the units.

The joint ports' TAP demonstrations for the Vision Motor Corporation's hydrogen fuel cell/plug-in electric on-road truck and terminal tractor began in late-2010, with testing of the two prototype vehicles anticipated to begin in 3rd Quarter 2011. The performance of these vehicles will be tested in various terminal and short-haul operations to evaluate their hauling capacity, range, speed, and reliability in the various duty cycles over an 18-month period.

The ports are also actively working with other technology developers as they prepare proposals for consideration through the TAP and anticipate additional zero emission technology demonstration projects to be brought forward for Board consideration later this year.

While these technology projects are underway, until they have successfully completed their prototype testing and are being produced for the commercial market, they are not yet considered viable options[2].

Further, through the TAP, the ports participated in regional and national efforts to develop advanced, lower emissions truck technologies including the national Hybrid Truck Users Forum (HTUF) and the California Hybrid Efficient and Advanced Truck (CalHEAT) research groups. Finally, the ports developed a port drayage truck duty cycle to provide technology developers with a detailed technical understanding of the performance requirements for a typical drayage truck.

2.2. The Ports' ZECMS Process

The concept of Zero Emission Container Movement Systems (ZECMS) has been under investigation for many years. The ports have been actively engaged or the lead agency in these evaluations.

In 2006, the ports evaluated various zero emission technologies through a Request for Proposals (RFP) process. The resulting evaluation report, issued in early 2008 by Cambridge Systematics, identified that

[2] TIAX LLC, *Technology Status Report – Zero Emission Drayage Trucks*, Prepared for the Port of Long Beach and Port of Los Angeles, June 2011.

none of the 13 technologies evaluated was deemed ready for deployment at that time. The process, however, provided valuable insight into the range of ZECMS approaches that could be pursued. As a follow-up to the RFP, and in response to unsolicited proposals by technology vendors, the Port of Long Beach (POLB) performed a right-of-way study to evaluate various routes for a potential fixed guideway system, identifying two potentially feasible routes between the ICTF and POLB's Pier A terminal. In mid-2009, the ports issued a Request for Concepts and Solutions (RFCS) which encouraged submissions of proposals to design, build, and operate a ZECMS between Pier A and the ICTF. The ports, aided by an independent team of technical experts from the Keston Institute for Public Finance and Infrastructure Policy at the University of Southern California (USC), reviewed seven proposals ranging from magnetic levitation (maglev), to linear-synchronous motor (LSM), to vacuum-propulsion technologies.

The USC Keston Institute presented their findings in mid-2010, concluding that none of the proposals were sufficiently mature to commit to a full-scale operational deployment or demonstrated they could deliver a reliable and financially sustainable system at this time. While the general level of proposed systems may have demonstrated experimental proof of concept in a laboratory environment, they all had shortcomings including immature technology, technology that was not proven or tested in port duty cycle applications, and/or technology that lacked a viable financial plan. Debrief interviews with several of the RFCS respondents indicated that additional research and development were needed on their proposed technology, as well as coordinated planning efforts with other regional stakeholders, including regulatory and transportation agencies.

2.3. Regional Zero Emissions Efforts

2.3.1 Metro's Freeway Major Corridor Study

In March 2005, following an extensive technical review and community outreach process, Metro completed the I-710 Freeway Major Corridor Study (MCS). The study analyzed existing and predicted congestion and mobility along the I-710 corridor in order to develop transportation solutions to preserve and enhance the quality of life of surrounding neighborhoods and communities. The study took into account projected increases in container volume at the ports of Long Beach and Los Angeles, the corresponding increase in container truck traffic volume along the I-710, as well as the physical condition of the I-710 freeway infrastructure. Priorities identified by stakeholders during the MCS process included:

- Improve air quality in communities adjacent to the I-710;
- Improve mobility, congestion and safety along the freeway corridor; and
- Assess alternative, "green" goods movement technologies.

The I-710 EIR/EIS studied 18 miles of the I-710 freeway between the Ports and the Pomona Freeway (SR-60). Four alternatives were analyzed in the EIR/EIS:

- No Build Alternative - As required by federal law, the "No Build Alternative" includes transportation improvement projects already programmed or committed to be constructed by the EIR/EIS planning horizon year of 2035;
- Ten Lane Facility - Widen the I-710 freeway to ten lanes for the length of the corridor;
- Ten Lanes and Four Separate Freight Lanes - Widen the freeway to ten general purpose lanes throughout the length of the corridor and add four separated freight movement lanes for exclusive use by conventional trucks;
- Freight Lanes Dedicated to Zero Emission Trucks - Includes all the improvements in the previous alternative, but requires use of zero emission technology to move goods in the freight lanes.

The results of the I-710 Corridor Project EIR/EIS were published in January 2009 in Metro's *Alternative Goods Movement Technology Analysis –Initial Feasibility Study Report*[3].

Two categories of zero emission technologies were assessed for potential I-710 application: automated fixed-guideway systems and battery electric trucks. The report characterized each category of alternative technology in terms of guideway requirements, propulsion, energy consumption, command and control, terminal interfaces, switching, sorting and storage, system operations, and system assurance.

In light of the apparent property requirements for deployment of an automated fixed-guideway technology at the ports and intermodal rail facilities, a new type of battery electric truck technology was considered that would interface with ports and rail terminals as conventional trucks do today, but would operate on a dedicated guideway subject to controls that safely optimize capacity. The report concluded that such a technology does not exist as a commercial product today, but would incorporate characteristics of existing freight and passenger technologies. It was also conceived that drayage trucks powered by electric motors could draw wayside electric power along the corridor and operate on battery power at the ports and intermodal rail facilities.

2.3.2 SCAG's Goods Movement Plan

The SCAG's Regional Transportation Plan (RTP) represents the "long-term investment framework for addressing the region's transportation and related challenges"[4]. An important effort under the 2008

[3] Final Report: Alternative Goods Movement Technology Analysis –Initial Feasibility Study Report, WBS ID:160.10.60, Los Angeles County Metropolitan Transportation Authority, January 6, 2009.

[4] 2008 Regional Transportation Plan, *http://www.scag.ca.gov/rtp2008/pdfs/finalrtp/f2008RTP_ExecSum.pdf*

RTP is development of SCAG's Comprehensive Regional Goods Movement Plan and Implementation Strategy which seeks to optimize the region's transportation system with the application of new technologies. This plan will include evaluation of all freight modes relative to economic efficiency, congestion mitigation, air quality improvements, and system security enhancements. The regional goods movement system defined through this plan will "feed" the upcoming 2012 RTP, which is also under development.

Specifically, SCAG's vision includes the introduction of a high-speed, high-performance regional transport system (HSRT). An HSRT system could potentially include new alternative, zero emission, technology-based systems that can provide enhanced throughput and reliability from the ports of Long Beach and Los Angeles to an inland port facility. The system would capitalize on the synergy of multiple uses on a single infrastructure by operating on shared alignments with a HSRT passenger system. Significant additional evaluation is required, especially with regard to the location of an inland port facility and the associated costs. In the 2008 RTP, SCAG estimated the cost to connect the ports to the HSRT to be $18 billion, with an implementation target of 2020.

3. Recommended Direction – A Roadmap to Zero Emissions

3.1. Candidate Source Categories

As described in Section 1, the ports identified the source categories where zero emission technologies best apply – specifically, container drayage conducted between the ports and destinations throughout the region, container handling at marine terminals, and locomotives used in switching and line-haul operations.

For the purpose of this discussion, container drayage is grouped into two modes:

- Short-Haul Drayage - This operation involves very short container moves from two to six miles in length. Cargo moves between the port terminals and the ICTF, which functions as the Union Pacific (UP) near-dock rail terminal, or nearby container yards are included within this category;
- Medium-Haul Drayage
  - Local Drayage - A high concentration of warehouses and truck terminals, as well as a major rail yard (Hobart), exist within 20 miles of the ports. These terminals include distribution centers in downtown Los Angeles, Compton, and Rancho Dominguez. For the purposes of this report, local operation is defined as cargo moves originating or terminating at the ports and having the other end point between six and twenty miles distance from the ports. According to drayage truck origin and destination surveys, approximately 50 - 60% of port drayage truck activity is captured in this range;

- Regional Drayage - At distances greater than twenty miles from the ports but within the South Coast Air Basin (SoCAB), large warehouse facilities are common and may be used to transfer goods for interstate delivery.

Container handling within a marine terminal involves a wide range of specialized CHE, each type of equipment performing a specific function. This equipment includes vehicles such as yard tractors, top handlers, side picks, and rubber tired gantry cranes. A review of the combined ports' emissions inventories indicates that 50% of CHE operating at the San Pedro Bay Ports consists of yard tractors that move containers within the marine terminals and intermodal facilities.

Locomotive activities include switching activities to build trains, occurring primarily within the port boundaries and intermodal yards, and line-haul activities, transporting trains along the rail corridors, typically to destinations outside of the SoCAB.

These four container movement modes – short-haul drayage, medium-haul drayage, cargo handling equipment, and rail locomotives – represent the four highest priority pathways on the road to zero emissions. The sections that follow will discuss the identification and evaluation of candidate zero emission technology options relative to these four priority container movement modes, culminating in recommended next steps in the zero emission roadmap.

3.2. Process to Identify Zero Emission Technology Options

As described in Section 2, the ports employed a structured process to develop the recommended roadmap to zero emissions, first identifying and screening, then evaluating the applicability, compatibility, feasibility, and economic viability of zero emission options at each step in a container's movement through the ports and into the region. Consistent with the principles identified in Section 1, this process included the following key components:

- Development of Operational and Performance Requirements – Characterization of the operations and performance of each segment of container movement, both in-port and on a regional level. This assessment included conducting detailed analytical studies of container drayage and yard tractor duty cycles to define performance requirements.
- Identification of Zero Emission Technologies - A compilation of technical and programmatic information relative to candidate zero emission technologies, including near term technologies undergoing development and demonstration through the TAP, as well as longer-term technologies identified during the ports' ZECMS RFCS process. In addition to technical and programmatic information provided by technology providers, the ports conducted independent

research and evaluation[5] of zero emission options to better understand their level of technical maturity, feasibility, and potential for near term commercialization.

- Evaluation of Candidate Zero Emission Technologies - For the candidate zero emission technologies identified as potentially applicable and compatible within a segment of port-related container movement, a detailed evaluation was performed using the evaluation criteria presented in Section 3.3 below.
- Recommendations – Recommendations relative to specific zero emission technologies that should be advanced by the ports at this time, including next steps.

Through this process, it became clear that due to differences in operational requirements and implementation issues encountered in various segments of goods movement, *there is no single zero emission technology solution that currently exists or is anticipated to become available that satisfies all of the stated principles and evaluation criteria.* A zero emission option for marine terminals will be different from a zero emission technology applied to container movement on a regional scale. This is because the operational requirements of container movement within a marine terminal environment are very different than those associated in moving containers along rail corridors to the edge of the SoCAB boundary or along public roadways from the terminal to the ICTF, downtown Los Angeles, or the Inland Empire. Unfortunately, there are no zero emission technology "silver bullets" that will provide a single solution that serves all stakeholder interests or requirements.

That being said, the port staff identified opportunities in which a zero emission technology that is not included in the near term zero emission roadmap could have a potential role in the longer term. Zero emission technologies being advanced in the near-term will preserve flexibility for future innovations. There are also paths along the roadmap that identify the incremental expansion of zero emission technologies across multiple goods movement segments and multiple source categories. Thus, while no single solution exists for a near term solution, technologies that are not fully developed today may have a more defined role in the future.

It is important to recognize that the identification and evaluation of zero emission options is a dynamic and ongoing process. The roadmap does not identify a specific end point or future state of technology – it is intended to identify steps in the ports' transition to zero emissions that can be supported today with the understanding that advancements in technology readiness and availability will continue to evolve and must be continually assessed. Thus, it is essential that the ports establish and work within a process framework that allows for technology assessment and reassessment, and fosters collaboration with port tenant, customer, regional, and regulatory stakeholders. The ports' TAP is the key element in this ongoing, dynamic process. Through the TAP, the ports will accelerate the verification or commercial

[5] Technology Status Report - Zero Emission Drayage Trucks, Draft Report, TIAX LLC, May 2011.

availability of zero emission technologies across all applicable source categories, through identification, evaluation, and demonstrations. *However, the principal objective of the zero emission roadmap is to identify next steps and get started now.*

3.3. Criteria for Evaluating and Prioritizing Zero Emission Options

In order to evaluate and prioritize candidate technologies and options for inclusion in the ports' roadmap for zero emissions, the ports defined seven decision criteria. These criteria were used to assess competing technologies for short-haul drayage and in-terminal container handling equipment. The evaluation criteria were developed under the guidance of the ports' principles and also derived from criteria used for the TAP to be consistent with the San Pedro Bay Standards. The criteria also favor options that could bring more immediate benefits and that faced fewer technical, operational, economic and implementation obstacles. Finally, the criteria will be used to uniformly evaluate additional technologies and other source categories in the future.

In developing recommendations, the port staff employed the following criteria:

- **Emissions Reduction and Health Risk Benefits** – the zero emission option's anticipated port-related emission and health risk reductions and contribution toward achieving the San Pedro Bay Standards. The magnitude of benefits derived from the zero emission solution should be commensurate with the investment required, i.e., evaluated on a "cost/benefit" basis with preference given to technologies with higher ratios of benefits to cost;
- **Constructability** – including infrastructure and utility requirements, availability of required space, and Right of Way (ROW) acquisition requirements with preference given to projects that can be integrated into the existing infrastructure or those with fewer barriers to construction;
- **Technology Readiness** – the level of technical maturity and feasibility, demonstrated reliability/durability, and commercial availability with preference given to more mature technologies so as to speed the pace of implementation;
- **Operations Compatibility** – the capability of candidate zero emission technologies to be integrated into ongoing port operations and duty cycles, as well as compatibility with existing operations with preference given to technologies that can more easily be integrated into existing operations;
- **Regional Scalability** – the ability of a port-scale zero emission solution to be incrementally expanded to a regional scale (i.e., in-port, port to ICTF, and expansion along corridors like I-710 between ports and downtown Los Angeles and beyond to the Inland Empire) favoring technologies that can be readily expanded to the regional scale;

- **Cost and Economic Sustainability** – the capital, operational, and life cycle cost, need for incentives or subsidies, and the potential to become economically competitive and sustainable relative to conventional container movement operations with preference given to cost-competitive projects;
- **Timeline** – the expected timeframe for zero emission technology demonstration, commercialization, regional expansion, etc. While the timeline is not used as a criterion to approve or reject technologies, it is used to prioritize actions. For the purpose of the zero emission roadmap, discrete timeframes were defined as follows:
  - Near Term timeframe: Within 3 years
  - Longer Term timeframe: Beyond 3 years

3.4. Zero Emission Options for Short-Haul Container Drayage

Two distinct options emerged from the ports' efforts to identify candidate zero emission options to replace or augment short-haul container drayage currently performed by trucks:

1. Deployment of on-road zero emission trucks, including but not limited to battery-electric trucks, zero emission hybrid-electric trucks, electric trucks powered by an overhead catenary system, or electric trucks using wayside power or LSM embedded in existing roadways or dedicated truck lanes;
2. Construction of an automated fixed guideway system incorporating technologies such as maglev or the adaptation of LSM to existing railroad tracks.

These options are described below, specifically the performance requirements and technology status for each, in addition to a recommended approach for moving forward.

3.4.1. Performance Requirements for Short-Haul Drayage Trucks

To successfully develop advanced zero emission trucks for short-haul drayage, vehicle manufacturers must understand the duty cycle requirements of port drayage trucks. To characterize port drayage duty cycle requirements in analytical terms, the ports developed and published detailed duty cycles for drayage trucks serving both the Port of Long Beach and Port of Los Angeles[6] using data obtained from instrumented trucks in actual container drayage service.

[6] Characterization of Drayage Truck Duty Cycles at the Port of Long Beach and Port of Los Angeles; Final Report, TIAX LLC, February 2011.

A typical short-haul drayage duty cycle includes three distinct driving modes:

Creep → Low Speed Transient → Short High Speed Transient

In analytical terms, the requirements of a typical short-haul container dray can be represented as follows:

- Average Duration of Short-Haul Container Dray: 39 minutes
- Average Truck Speed: 7.7 mph
- Maximum Truck Speed During Haul: 42.2 mph
- Average Short-Haul Distance from Port: 5 miles
- Number of Stops During Dray: 31 stops (traffic control, etc.)
- Percentage of Time Spent Idling: 44%

The short-haul duty cycle requirements were then used to define the minimum performance requirements for zero emission drayage truck:

- 80,000 lbs. gross combined weight rating (GCWR)
- 50+ mph top speed with full load
- 20% or greater gradeability at vehicle launch
- 6% gradeability[7] at 40+ mph and 80,000 lbs. GCWR
- Operating time between refueling or recharging must allow for one complete shift (approximately 8 hours) or have comparable fill times as diesel trucks.

Note that the gradeability at 40+ mph is based on the characteristics of the three major bridges in the port area (Gerald Desmond Bridge, Vincent Thomas Bridge, and Commodore Schuyler F. Heim Bridge). It is possible to use other routes to avoid the steep grades on the bridge, possibly lowering the specified grade requirements.

3.4.2 Development Status of Zero Emission Short-Haul Trucks

Vehicles employing partially electrified drive trains have seen dramatic growth in the light-duty market over the last ten years with the commercialization of various hybrid-electric passenger cars. The medium- and heavy-duty markets have also shown recent trends toward electrification of drive trains in

[7] Based on Gerald Desmond Bridge approach grade, Gerald Desmond Bridge Replacement Project Traffic Impact Study, October 2009

both on-road and off-road applications. Several manufacturers are pursuing commercialization of heavy-duty electric trucks that have the potential to meet the basic operational requirements for short-haul drayage trucks.

As identified earlier, two electric truck manufacturers, Balqon and Vision Industries, are currently working with the ports to test prototype on-road electric trucks that meet the CARB definition for zero emission. The Balqon and Vision Industries prototype technologies are being used as examples to characterize the current state of development for zero emission trucks that are potentially suitable for short-haul drayage service at port terminals.

- Balqon Corporation Battery-Electric Drayage Truck - In 2007, the Port of Los Angeles and AQMD entered into a contract with Balqon Corporation to develop and demonstrate a battery-electric truck that could operate within and outside terminal facilities in both on-road and off-road applications. The initial prototype truck, the Nautilus E-30, was completed and tested in early 2008, primarily as an off-road yard tractor. Based on an assessment of the prototype truck's performance by port and AQMD staff, it was determined that an upgraded version of the E-30 had the potential to meet the performance requirements for an on-road short-haul drayage truck. In June of 2008, the Port of Los Angeles approved Resolution Number 08-6571[8], thereby entering into a multi-phased test program with Balqon that ultimately includes the purchase and delivery of five E-30 battery electric on-road drayage trucks that could be used for short-haul operations. This multi-phased test program has been underway primarily focusing on enhancements to the batteries and battery management system. Initial tests have been conducted on yard tractors. Because yard tractors and short haul drayage trucks have similar electric drive system components and duty cycles, many of the lessons learned and potential enhancements, including those made to the batteries and BMS, would assist in the development of the on-road units. Balqon is currently in production of the first on-road unit for short-haul operations, which will be delivered in the third quarter of 2011.

- Vision Industries Hybrid-Electric – The Vision Industries Tyrano™ on-road truck is a special type of zero emission hybrid-electric vehicle that uses battery power for propulsion and an on-board hydrogen fuel cell system to recharge the vehicle's batteries. The vehicles being tested under the ports' TAP include a plug-in option for recharging the batteries; however Vision has stated that the fuel cell can be relied upon to recharge the batteries in lieu of plugging into the electrical grid. The vehicle's performance characteristics, including horsepower, torque, gradeability, etc., are substantially similar to the Balqon E 30 described above. Based on Vision's preliminary vehicle specifications, the Tyrano™ hybrid drive system has the potential to provide adequate horsepower and torque to meet the needs of drayage service. Vision engineers report

[8] *http://www.portoflosangeles.org/Board/2008/June/061908_Special_Meeting_Item1_trans.pdf*

that the Tyrano™ will have a rated gradeability of 13% when fully loaded at 80,000 GCWR; this should enable it to meet all grades that will be encountered in short-haul drayage trucking. One potential performance-related issue is that the Tyrano™ day cab tractor weighs approximately 17,500 pounds; this is approximately 2,000 pounds heavier than a comparable diesel tractor. However, Vision engineers point out that the Tyrano™ tractor's weight distribution has been optimized to help prevent overloading of the front axle when heavy loads are moved. In July 2011, Vision delivered the demonstration unit and the 18 month in-use demonstration was initiated.

Battery and zero emission hybrid electric trucks are expected to initially cost more than double that of a conventional diesel Class 8 on-road drayage truck. The majority of the incremental cost is associated with the battery storage system. Most heavy-duty electric truck manufacturers specify advanced lithium chemistry batteries. These batteries offer the benefits of high levels of electrical energy storage capacity, long life, and lower weight as compared to other battery types. However, at today's production rates, lithium chemistry automotive batteries are the single most expensive component of the electric drive system. As additional hybrid electric and battery electric passenger cars enter the marketplace, it is anticipated that increased production rates, production automation, and competitive market forces will result in economies of scale that ultimately lower the cost of electric vehicle batteries. This is already being seen as it pertains to lithium-ion batteries entering the marketplace.

The reliability and durability of heavy-duty electric trucks in a short-haul port duty cycle have yet to be proven. While the prototype electric trucks are anticipated to be capable of meeting the combination of payload and grade performance requirements necessary for local drayage operation, testing of the initial Balqon units have shown inadequate speed at grade while under load and limited range, indicating further design improvements are needed. To assess the technical capability of the Balqon and Vision Tyrano, a test program is being developed for the TAP demonstration that employs the truck over an extended period of time in actual, fully loaded container drayage service on typical routes.

While Balqon and Vision are used as examples in this report because they are currently being evaluated by the ports, they are not the only Class 8 zero emission truck options in development. The AQMD is currently funding the development of Class 8 battery electric trucks, and manufacturers of Class 5 - 7 battery electric trucks have expressed confidence that existing electric drive systems are scalable to meet Class 8 container drayage operational requirements. Thus, it should not be construed that staff is recommending any specific vendor or vehicle – the reference to electric trucks in the zero emission roadmap includes all electric trucks that meet port requirements and is not limited to these two options.

With respect to electric trucks designed to operate using an off-board electric power source, such as electric trucks powered by an overhead catenary system (OCS) or wayside power, these technologies are not being dismissed as options. These off-board power systems may offer the potential to extend the range of the zero emission trucks beyond what can be provided by the on-board battery system, and can be developed based on the successes and/or lessons learned from the current electric or hydrogen-electric hybrid projects. However, it is important to recognize that commercially available linear induction/linear synchronous motor technologies do not currently exist. While OCS has been widely used in on-road transit bus applications, the need for and benefits of OCS as compared to electric trucks using on-board energy storage (i.e., batteries) for *short-haul drayage* have yet to be identified or evaluated for operation at the San Pedro Bay ports. It is recommended that the ports view the zero emission option of electric drayage trucks as inclusive of all electric power technologies, recognizing that the implementation timeline of each technology will vary, and that some currently infeasible technologies may become viable in the longer term or for range extension, as long as there is flexibility in the implementation to allow for future advancements.

3.4.3. Performance Requirements for Fixed Guideway Systems

The construction of a *fixed guideway* to connect marine terminals with near-dock intermodal facilities as an alternative to zero emission trucks was the predominant theme in the responses received under the ports' RFCS. Technologies proposed for operation on a fixed guideway include maglev propulsion systems, linear induction motor technology (without levitation), vacuum propulsion systems, and OCS. While the details of each propulsion technology vary, the common attribute is that containers are conveyed along a dedicated guideway that requires construction of new port infrastructure.

Because a fixed guideway represents new infrastructure and provides dedicated connectivity between the port terminals and near-dock rail facilities, the typical duty-cycle requirements corresponding to short-haul drayage operations do not necessarily apply. Instead, container movement requirements for a fixed guideway can be specified in terms of connectivity and throughput. To replace short-haul drayage service currently performed by drayage trucks, a fixed guideway option will need to have the following attributes:

- Connect the 13 existing marine container terminals spread throughout both ports to multiple near-dock intermodal facilities;
- Not impede existing on-dock rail or other operations at port terminals or operations at near-dock intermodal facilities;
- Be cost competitive in a reasonable timeframe with existing short-haul drayage services;
- Offer container throughput capacity that equals or exceeds marine terminal drayage requirements.

3.4.4. Development Status of Fixed Guideway Systems

During the ports' RFCS process, an evaluation team comprised of staff from each port, the Alameda Corridor Transportation Authority (ACTA), and a panel of experts selected by the Keston Institute of USC concluded:

- None of the systems proposed are sufficiently mature to commit to a full-scale operational deployment at this time;
- Additional testing that simulates the port environment is needed;
- A full understanding of port duty cycles was absent from all responses;
- None of the submissions adequately addressed the risks of insufficient market demand; and
- Technology and financial risk cannot be fully evaluated until the robustness and reliability of the systems have been demonstrated.

It is possible, and even likely, that issues involving insufficient technology maturity can be resolved through additional research and development. However, constraints imposed by ongoing operations at port terminals present integration issues that may render a fixed guideway solution impractical compared to trucks for short-haul.

To effectively replace current container movement operations, a fixed guideway would need to provide connectivity to at least 13 marine terminals and several near dock intermodal facilities which would require a virtual "web" of dedicated guideways. The method to deliver containers to the guideway, load containers onto the guideway at the marine terminals, and unload containers at the near-dock intermodal facility is currently undefined and must be resolved so as to not adversely impact port terminal and rail yard operations. In addition, construction of a fixed guideway, including elevated guideways, would require acquisition of terminal right-of-way and potentially acquisition of private right-or-way which may be impractical and prohibitively expensive.

Further and very importantly, a fixed guideway solution does not provide regional scalability and connectivity. In order to significantly reduce emissions and make progress toward meeting the ports' goals identified in the San Pedro Bay Standards, a zero emission option must have scalability and connectivity throughout the region, and not be applied only to discrete marine terminals or intermodal facilities near the ports. A zero emission option that is only able to capture operations between the marine terminals and intermodal facilities will, at best, only be able to reduce 0.4% of port-related DPM emissions; whereas if the zero emission option is scalable to the region, it could be capable of reducing 19% of port-related DPM emissions.

From an economic feasibility perspective, a fixed guideway option must compete with current drayage services performed using trucks. If the cost to use the fixed guideway option is greater than the drayage truck rates, then it will not be able to compete in the market, and will therefore not be financially viable. Fixed guideway concepts are the most expensive zero emission options, requiring significant capital investment for construction costs, acquisition of right of way, and loss of revenue for physical land area dedicated to the loading stations. Some of the respondents to the RFCS understated these costs. Hence, the RFCS review team concluded that the commercial financing assumed by some of the respondents may not prove to be readily available at terms that would enable a financially sustainable technology deployment. The conclusion of the port evaluation team was that, under best case assumptions regarding growth in container volume and share of container drayage market capture and absent environmental regulation or significant subsidies, a fixed guideway option will have difficulty competing economically with conventional truck drayage.

A variation on the fixed guideway concept is to adapt LSM to be integrated into existing rail tracks connecting marine terminal on-dock rail facilities with near-dock intermodal rail facilities. This concept offers the potential benefits of lower capital development costs and eliminates right-of-way acquisition issues. LSM technology will be further discussed in Section 3.7 – Zero Emission Options for Regional Rail Locomotives.

3.4.5 Evaluation of Zero Emission for Short-Haul Drayage

The two zero emission options for short-haul drayage, electric trucks and fixed guideway system, were evaluated using the evaluation criteria defined in Section 3.3. The result of this evaluation is provided in Table 1 and discussed below.

Table 1: Assessment of Zero Emission Options for Short-Haul Drayage

Evaluation Criterion	Electric Trucks	Fixed Guideway
Emissions and Health Risk Reduction	Excellent	Excellent
Constructability	Excellent	Poor
Technology Readiness	Satisfactory	Poor
Operations Compatibility	Good	Unacceptable
Regional Scalability	Satisfactory	Unacceptable
Cost and Economic Sustainability	Good	Unacceptable
Timeline for Implementation	Satisfactory	Poor

Excellent Good Satisfactory Poor Unacceptable

Each evaluation criterion is discussed below relative to the two general options:

- Emissions and Health Risk Reduction – both an electric truck and fixed guideway system offer zero emission container transport. It should be noted, however, that a fixed guideway system implementation timeline is significantly longer than the deployment of electric trucks; thus, emission and health risk reductions will be realized sooner under the electric truck option, contributing to achievement of the San Pedro Bay Standards;
- Constructability – Battery electric trucks operate on existing roadways and require no additional right of way or significant infrastructure development. Electric trucks using an OCS or wayside power would require construction of additional infrastructure; however, this is a potential longer term option for short-haul drayage if needed to extend the range beyond what can be provided by the on-board battery system. A new fixed guideway requires acquisition of right of way both within and outside of port boundaries as well as construction of the actual guideway which must connect to all 13 container terminals, the near-dock rail yard and possibly other near-port destinations;

- Technology Readiness – battery electric trucks are being demonstrated today with the goal of moving towards commercialization. Fixed guideway technologies, such as maglev and LSM are in the initial research and development stage of technical readiness;
- Operations Compatibility – Electric trucks, especially those powered by an on-board energy source such as batteries, can be seamlessly integrated into ongoing short-haul drayage operations assuming they have adequate range to perform the work and can be recharged in an acceptable amount of time. A fixed guideway solution would require significant changes to container handling practices within a marine terminal environment, including but not limited to container loading and unloading from the fixed guideway;
- Regional Scalability – Electric trucks, when operational, may be deployed throughout the SoCAB, and development of technology to extend the operational range of electric trucks is ongoing. A fixed guideway would be isolated to the specific locations where it is connected, and therefore does not offer the same level of flexibility and regional scalability;
- Cost and Economic Sustainability – Electric trucks currently carry a price premium and successful deployment of large numbers of zero emission trucks will most likely require funding incentives on an interim basis. It is assumed that such incentives will be made available, as they have been in the past for alternative fuel vehicles. Economies of scale, especially in high cost components such as batteries, will reduce the incremental cost of an electric truck as compared to a conventional diesel vehicle. A fixed guideway system requires significant capital development expenditure and must compete with drayage trucks performing short-haul drayage. The results of the ports' RFCS evaluation suggest a fixed guideway system is not economically competitive for short-haul drayage and not financially sustainable barring significant on-going cost subsidies;
- Timeline for Implementation – Electric trucks are undergoing demonstration in port duty cycles now and more zero emission truck concepts are expected to be demonstrated in the near future. A fixed guideway solution will require many additional years of research and development, design, environmental planning, and construction.

3.4.6 Recommendations for Short-Haul Drayage

The first critical piece in the zero emission roadmap is to continue the demonstration and refinement of zero emission, battery electric trucks for short-haul drayage operations by conducting technical evaluations and testing under the TAP. The goal of these efforts is to ensure the technologies can meet the demands of the port duty cycle, provide the technology developers with a test bed to refine their system designs, and ultimately to accelerate commercialization of zero emission trucks for port operations. *Demonstration and commercialization of zero emission trucks is the #1 priority as it relates to implementing zero emission technologies for short-haul drayage.*

Electric trucks offer:

- Seamless integration into ongoing port operations and offer the highest level of operational flexibility;
- Can be incrementally integrated into port drayage operations;
- Offer flexibility for scaling up to meet the regional needs;
- Do not require construction of new infrastructure or acquisition of right-of-way; and
- Appear economically viable with a high likelihood of self-sustainability as anticipated economies of scale and market forces lower vehicle acquisition costs.

In the near term, the demonstrations of zero emission trucks that are currently underway through the TAP are designed to address the need for zero emission, battery electric technologies for short-haul drayage. The Vision Tyrano truck was delivered in July 2011 and the Balqon truck will be delivered by 3rd Quarter 2011. Both trucks will undergo an 18-month demonstration period in accordance with an approved Demonstration and Test Plan. In addition, the ports will continue to evaluate new technology options by proposers through the TAP. Industry representatives will participate in these projects as demonstration partners and in an advisory capacity, along with the TAP Technical Advisory Committee (TAC), which includes the ports, EPA, CARB and AQMD.

In the longer term, the ports could:

- Continue to move forward with TAP demonstrations of advanced zero emission technologies for short-haul drayage, including conducting broader operational and durability testing, as needed;
- Promote improvements in battery technologies through the TAP;
- Identify funding support for additional demonstration tests;
- Work with industry to evaluate operational compatibility of larger-scale zero emission truck deployment;
- Assist with identifying funding support for purchases of zero emission trucks;
- Assess the need for battery charging and hydrogen fueling infrastructure with larger-scale zero emission truck deployment, and assist as needed and appropriate; and
- Evaluate overhead catenary or other wayside power systems for short-haul drayage, considering at a minimum, the benefits that could be offered beyond the capabilities of a zero emission truck with an on-board battery system, the cost, and the operational constraints.

3.5. Zero Emission Options for Medium-Haul Container Drayage

Medium-haul drayage has been defined as having two subcategories: local drayage, within 20 miles of the ports, and regional drayage, to destinations 20 miles beyond the ports but within the SoCAB.

The implementation of zero emission options beyond the ports' boundaries presents an array of challenges far greater than those associated with short-haul container movement. Outside the ports, issues such as right of way, jurisdictional authority, infrastructure requirements, and particularly cost become primary issues that must be resolved before any specific zero emission option can be deemed fully viable. The implementation of zero emission options beyond the ports' boundaries will require the coordinated efforts of multiple regional stakeholders, including but not limited to Metro, SCAG, Gateway Cities, and AQMD. Therefore, staff recommends that collaboration with regional stakeholders be the first step in a zero emission roadmap for medium-haul container drayage.

3.5.1 Performance Requirements for Medium-Haul Drayage

Medium-haul drayage consists primarily of the movement of cargo along local and regional freight corridors. Typically, medium-haul drayage includes container moves originating or terminating at the ports and having the other end point of the move between six (6) and 60 miles in length - this range effectively covers drayage operations between the ports and distribution centers in the Inland Empire.

While short-haul drayage can be typically characterized by a single duty cycle, medium-haul drayage, from an operational and performance requirements standpoint, is comprised of two duty cycles, represented as follows:

Local Dray (6 to 20 miles) - Creep → Low Speed Transient → Long High Speed Transient

Regional Dray (20+ miles) - Creep → Low Speed Transient → High Speed Cruise

The primary difference between the local and regional cycles is the duration of the high speed portion of the duty cycle. However, as shown below, the average length of a regional medium-haul dray is *five times* that of a local haul:

	Local Haul	Regional Haul
• Average Duration of Container Dray:	64 minutes	118 minutes
• Average Truck Speed:	10.2 mph	27.3 mph
• Maximum Truck Speed During Haul:	48.7 mph	57.6 mph
• Average Medium-Haul Distance from Port:	11 miles	54 miles
• Number of Stops During Dray:	46 stops	33 stops
• Percentage of Time Spent Idling:	41%	25%

The duty cycle requirements for medium-haul drayage, especially those conducted along regional corridors, are significantly more demanding on a truck compared to the short-haul duty cycle discussed in the preceding section. Medium-haul increases the range requirements of a zero emission technology by an order of magnitude compared to short-haul, and in the case of electric trucks, pushes the limits on range that can reasonably be expected from today's state-of-the-art battery-electric drive systems.

Also, drayage truck operations on a local or regional scale are conducted with greater periods of sustained, high speed operation. High speeds under heavy loads quickly consume energy stored within a vehicle's battery pack, dramatically reducing the electric truck's overall range.

3.5.2. Technology Development Status for Medium-Haul Drayage

To expand the capabilities of zero emission drayage trucks beyond the short-haul duty cycle, the introduction of additional zero emission technologies that substantially increase the vehicle's range will be required. Candidate zero emission technologies to extend the range of an electric truck include:

- Extended range battery packs through advanced battery technology, additional storage, or maximizing battery efficiency;
- Augmentation of on-board battery storage, such as hydrogen fuel cells; and
- Use of wayside power, including OCS and incorporation of linear inductive motors or LSM embedded in the roadway pavement.

Current battery technologies do not provide adequate range at a reasonable cost. While efforts are being made to improve battery technologies, no cost-effective options are expected to become available for the Class 8 truck application in the near term. Using an on-board fuel cell as a range extender will be tested by the ports Vision Tyrano truck project starting later this year and continuing for an 18-month demonstration period, however reliability in the short-haul application must first be proven before proceeding with a longer range test. OCS has been used for buses that travel along fixed routes. While the technology is potentially applicable to zero emission Class 8 trucks, further testing would be necessary to determine how such a system could be integrated into existing operations given the wide variety of routes and destinations for drayage trucks throughout the region. Further, an electric truck would be needed to connect to the system, and as stated previously, no such truck is commercially available at this time. A demonstration of this technology could be a logical follow-on after the short-haul drayage truck demonstrations have been conducted. Finally, application of wayside power embedded in the roadway to power electric trucks has never been tested for this type of operation. Development of a system would require significant research and development work before it could be implemented on a large scale.

3.5.3 Evaluation of Zero Emission Options for Medium-Haul Drayage

The criteria established by the ports to evaluate candidate technology options could be used to evaluate technologies for medium-haul drayage. As identified above however, medium-haul drayage is not just a port issue and criteria development and technology evaluation must be conducted in collaboration with regional stakeholders such as Metro, SCAG, Gateway Cities, and AQMD. The ports will seek to work with these and other stakeholders to develop collective criteria to evaluate regional zero emission technology options.

3.5.4 Recommendations for Medium-Haul Drayage

Zero emissions options addressing medium-haul drayage must be compatible with other solutions being developed for the region. Therefore, development of strategies will require a broad-based partnership to make zero emission options a reality.

In the near term, the ports should focus their efforts on the following:

- Establish a regional partnership including Metro, SCAG, Gateway Cities, AQMD, and others and work together to define regional zero emission freight transport needs and develop criteria for evaluating options for moving forward with zero emission technology on a regional scale;
- Build on and leverage the technology platform demonstrated for short-haul drayage;
- Work collaboratively with the regional partners to identify and evaluate specific range extension options for zero emission truck technologies, including hybridization, in-road LSM and OCS; and
- Work with the regional partnership to identify potential funding sources.

In the longer-term, the ports should work with the regional partnership to implement the agreed upon regional strategy, which could include:

- Work on regional zero emission freight strategy implementation, including demonstrating transitional technologies and technologies to extend zero emission truck range;
- Assist with zero emission truck deployment by identifying funding opportunities and assisting with charging, wayside power or hydrogen fueling infrastructure as appropriate; and
- Collaboration on further improvements in battery technologies.

3.6. Zero Emission Options for Cargo Handling at Marine and Intermodal Terminals

Container movement through a marine or intermodal terminal is currently performed by various types of CHE. CHE includes all vehicles and equipment that move cargo, containers, and bulk materials to and from marine vessels, railcars, and on-road drayage trucks.

At existing marine or intermodal terminals, the pathway to zero emission operations is likely to occur through the incremental transition of existing types of CHE and vehicles to zero emission operation, similar to the path recommended for electric short-haul drayage trucks. It is also probable that a terminal that transitions its fleet of conventional CHE to electric operation would at some point consider electrifying the terminal and/or converting some portion of their terminal to a semi-automated container movement system.

3.6.1 Zero Emission Cargo Handling Equipment

Due to the diversity of cargo handling requirements within a marine or intermodal terminal, there is a wide range of specialized CHE, each type of equipment performing a specific function. The majority of the CHE can be classified into one of the following equipment types:

- Forklift
- Rubber Tired Gantry (RTG) crane
- Side Pick
- Other equipment[9]
- Sweeper
- Top Handler
- Yard Tractor

A breakdown of CHE operating at the San Pedro Bay Ports is shown in Table 2[10]:

Table 2: CHE Composition at the San Pedro Bay Ports

CHE Type	POLB		POLA		Combined Ports	
	# of units	% of CHE Fleet	# of units	% of CHE Fleet	# of units	% of CHE Fleet
Forklift	252	19%	538	27%	790	24%
RTG	89	7%	108	5%	197	6%
Side Pick	34	2%	40	2%	74	2%
Sweeper	22	2%	15	1%	37	1%
Top Handler	154	11%	154	8%	308	9%
Yard Tractor	713	52%	962	48%	1,675	50%
Other	94	7%	183	9%	277	8%
Total	1,358	100%	2,000	100%	3,358	100%

[9] Other equipment includes but is not limited to construction-related equipment, non-container moving cranes, miscellaneous warehouse equipment, and utility and support vehicles.

[10] Source: 2009 POLA and POLB Emissions Inventories

The relative contribution of each type of CHE to the emissions at the combined ports is shown in Table 3. Yard tractors that comprise 50% of the CHE fleet account for 51% of total CHE DPM and 42% of total CHE NOx emissions. Top handlers, which comprise only 9% of the total CHE fleet, account for 22% of total CHE DPM and 27% of total CHE NOx emissions. In contrast, forklifts which account for 24% of all CHE represent only 5% of total CHE DPM and 8% of total CHE NOx emissions.

Table 3: Relative Emission Levels of CHE Types at the Combined Ports

CHE Type	DPM (tpy)	% DPM of Total CHE Fleet	NOx (tpy)	% NOx of Total CHE Fleet
Forklift	2	5%	102	8%
RTG	4	9%	142	11%
Side Pick	1	2%	41	3%
Sweeper	0	1%	8	1%
Top Handler	9	22%	350	27%
Yard Tractor	22	51%	560	42%
Other	4	10%	115	9%
Total	42	100%	1,318	100%

3.6.2 Performance Requirements for Cargo Handling Equipment

A challenge with implementing zero emission technologies for CHE is the diversity of CHE duty cycle requirements, which vary by type of equipment. Performance requirements for specific types of CHE are shown below in Table 4:

Table 4: Typical Performance Requirements for Port Cargo Handling Equipment

			POLA			POLB		
CHE Type	Typical Duty Cycle	CHE Operations Description	Engine Size (avg. HP)	Load Factor	Average Hours per Year	Engine Size (avg. HP)	Load Factor	Average Hours per Year
Forklift	Operate two 6.5-hour shifts per day, 5-6 days per week.	Used to move cargo, truck chassis, or other equipment short distances for placement on or removal from stacks	105	0.3	848	106	0.3	426
RTG	Operate two 7-hours shifts, 4 days per week.	Used to stack containers, or move containers on and off yard trucks	543	0.2	1,155	682	0.2	970
Side Pick	Operate two 6.5-hour shifts per day, 5-6 days per week.	Used to stack containers, move containers from one area of the terminal to another, or move containers on and off yard trucks	208	0.59	1,055	181	0.59	602
Sweeper	Operate two 8-hour shifts per day, 5-6 days per week.	Used to clean paved areas in the yard	128	0.68	293	118	0.68	397
Top Handler	Operate two 6.5-hour shifts per day, 5-6 days per week.	Used to stack containers, move containers from one area of the terminal to another, or move containers on and off yard trucks	290	0.59	1,534	294	0.59	1,450
Yard Tractor	Operate two 8-hour shifts per day, 5-6 days per week.	Used to move containers to and from ships or rail, move containers within the terminal, and move containers to and from RTG cranes for placement on or removal from stacks	215	0.39	1,699	189	0.39	1,301
Other	Various special purpose duties	Includes a variety of equipment types including aerial lifts, rail-car movers, and heavy duty off-highway trucks	37 - 401	0.43 - 0.55		37 - 401	0.43 - 0.55	

It is noteworthy that the duty cycle requirements for yard tractors have some similarities to the near-dock/short-haul duty-cycle for on-road drayage trucks discussed in preceding sections. This similarity in operational requirements suggests that zero emission technology solutions that are feasible for short-haul drayage have a high probability of being applicable to yard tractors within a marine terminal.

3.6.3 Technology Status for Zero Emission Cargo Handling Equipment

All of the ship-to-shore gantry cranes in both ports are powered by electricity. In addition, the ports have aggressively advanced technologies that reduce or eliminate emissions from other CHE operating within the terminals. This includes demonstration of bridge technologies on the path towards zero emissions, such as diesel-electric hybrid. These technologies not only provide incremental emission reduction benefits in the near-term, they can provide useful information to benefit the development and demonstration of future advanced technologies. Low emission technology CHE projects undergoing demonstration through TAP are summarized below in Table 5:

Table 5: Interim Technologies Toward Zero Emissions Demonstrated Through TAP

Technology Category	Project	Anticipated Emission Reductions
Hybrid Technologies	Vycon REGEN System for RTGs	25% DPM; 30% NOx; 30% CO2
	Capacity Plug-In Hybrid Yard Tractor	60% CO2
	Diesel-Electric Hybrid Yard Tractor	93% DPM; 5% NOx
	Railpower EcoCrane RTG	75% DPM and NOx
Alternative Fuel Technologies	LNG Yard Tractors (2005 Model Year)	100% DPM; +21% NOx; 18% CO2
	APT Emulsified Biodiesel	40% DPM
Retrofit and Exhaust After-treatment Technologies	Rypos Active Diesel Particulate Filter	85% DPM

In addition, the ports are also conducting demonstrations of zero emission technologies, as identified below:

- Balqon Lead-Acid Battery Yard Tractor;
- Balqon Lithium-Ion Battery Yard Tractor;
- Balqon Lithium-Ion Battery Yard Tractor integrated with a Vision Motor Hydrogen Fuel Cell; and
- Vision Motor Hydrogen Fuel Cell/Plug-In Electric Yard Tractor.

As discussed in Section 3.4.2, the Port of Los Angeles and AQMD contracted with Balqon to develop and demonstrate a battery-electric truck. The Port of Los Angeles has ordered Nautilus E-20 units with lead acid batteries and is currently releasing them in a demonstration program at non-container terminals where the duty cycle is less demanding. The next generation E-20 units are equipped with lithium ion batteries, some with range extending hydrogen fuel cells for on-board charging. These next generation E-20 units will be released for demonstration at a trucking company-based container facility with plans to demonstrate them at marine container terminals thereafter. Vision Motor's Hydrogen Fuel Cell/Plug-In Electric Yard Tractor is currently being produced and is expected to be tested at a trucking company-based container facility in 2011.

Manufacturers of conventional diesel yard tractors have also expressed interest in offering electric versions of their existing product line; thus, it is anticipated that additional manufacturers will enter the electric yard tractor marketplace in the future.

For RTGs, electric conversion kits are commercially available and have been used in other countries. RTGs can be electrified by retrofitting the units with a kit (cable reel, transformer and interface) to allow the RTG to utilize grid electricity. The Port of Los Angeles is currently pursuing an electric RTG crane project with one terminal operator; two terminal operators in Port of Long Beach had initially pursued RTG crane electrification projects and were awarded $2.5 million grants from the port in 2007, however both projects were cancelled due to financial constraints and/or a decision by the terminal operator to wait until the project would better fit into future terminal plans.

Similar to electric RTGs, rail mounted gantry cranes or RMGs, are also powered by electric grid power. RMGs travel forward and backward along a fixed rail. RMGs are currently in use in rail yard operations at ICTF and terminal operations at APL in Port of Los Angeles.

3.6.4 Evaluation of Zero Emission Technologies for Cargo Handling at Marine Terminals

The evaluation criteria introduced in Section 3.3 were applied to individual CHE types at the "vehicle level" to identify and prioritize zero emission CHE opportunities for existing marine and intermodal terminal operations. Note that the evaluation included only those equipment types for which staff had information at this time on electrification or zero emission technology options. As part of recommended next steps, zero emission technologies will be identified and advanced for all CHE types. Note that the "regional scalability" evaluation criterion does not apply when evaluating zero emission options for CHE, since these vehicles are a captive fleet at a terminal. The evaluation results are provided below in Table 6.

Table 6: Evaluation of Marine and Intermodal Terminal Cargo Handling Options

	Zero Emission Cargo Handling Equipment			
Evaluation Criteria	**Yard Tractor**	**RTG**	**RMG**	**Forklift**
Emissions and Health Risk Reduction	Excellent	Excellent	Excellent	Good
Constructability	Excellent	Good	Good	Excellent
Technology Readiness	Satisfactory	Excellent	Excellent	Satisfactory
Operations Compatibility	Good	Good	Satisfactory	Good
Regional Scalability	N/A	N/A	N/A	N/A
Cost and Economic Sustainability	Good	Good	Good	Good
Timeline for Implementation	Satisfactory	Good	Good	Satisfactory

Excellent Good Satisfactory Poor Unacceptable

A discussion regarding CHE relative to each criterion is provided below:

- Emissions and Health Risk Reduction – All of the zero emission CHE offer significant emissions reduction. It should be noted, however, that many of the forklifts already operate on propane, and a few of the smaller forklifts are battery powered. Therefore, the emissions reduction potential for forklifts is slightly less than for the other diesel equipment.

- Constructability – Zero emission yard tractors and forklifts would operate on the existing terminals and would only require installation of electric battery charging capabilities, if necessary. Electric RTGs and RMGs would require construction of electrical infrastructure, potentially guard rail systems to protect the infrastructure and, in the case of RMGs, construction of rail tracks.

- Technology Readiness – Zero emission yard tractors are in the development stage, as battery-electric and zero emission hybrid-electric yard tractor prototypes are undergoing development and demonstration in port-related operations. Zero emission forklifts are commercially available for the smaller horsepower range (~100 hp), but development work is needed to apply zero emission technology to heavy-duty forklifts in port container terminal operations. Electric RTG retrofits, electric RMGs and forklifts are commercially available and have been used in port-related operations.

- Operations Compatibility - Electric yard tractors and forklifts offer a high level of compatibility with ongoing terminal operations and can be seamlessly integrated into a marine or intermodal terminal incrementally. Accommodation will need to be made for recharging, as needed; however a goal of the TAP demonstrations will be to evaluate any impacts on operations from recharging. When integrating electric RTGs and RMGs into operations, some of the current flexibility offered by traditional diesel-powered RTGs will be lost. In particular, the installation of electric infrastructure and rail tracks for RMGs requires that the electric RMGs be fixed to a specific location which will limit the ability to make adjustments to yard configurations. Some terminal operators have stated that this inflexibility is incompatible with their current operations, and therefore further evaluation on how this technology could be integrated into existing operations may be needed in some cases. Converting an RTG to electric requires electrical infrastructure, but it is only semi-fixed and therefore provides greater flexibility for future yard re-configuration. In addition, as an interim measure, the ports are continuing demonstration of low-emission technologies for RTGs that are not converted to a zero emission configuration.

- Cost and Economic Sustainability – In the near term, electric CHE will most likely require incentives to partially offset the higher capital acquisition costs of battery electric vehicles and equipment. From a life cycle cost perspective, it is anticipated that the terminal operators will realize lower operating costs tied to lower fuel costs and lower equipment maintenance costs.

  Electric yard tractors also share common technology and components with electric short-haul drayage trucks; this commonality leverages prior investments and should generate manufacturing economies of scale, reducing future costs for vehicle acquisition. It is also expected that electric drive system designs and components developed for yard tractors can and will be adapted to other types of CHE, such as top handlers and side picks. This transferability will further leverage zero emission technology investments.

- Timeline for Implementation – Electric yard tractors are undergoing demonstration in port duty cycles now and more concepts are anticipated to be demonstrated in the near future. Electric RTGs, RMGs and smaller forklifts are commercially available. Electric RTGs or RMGs are currently being implemented in new or redeveloped terminal projects.

3.6.5 Recommendations for Cargo Handling Equipment

The ports recommend the following near-term course of action:

- Continue to sponsor the demonstration of electric CHE by port tenants in cargo handling operations. Electric yard tractor prototypes are currently under development through the TAP program, and the priority of port staff is to demonstrate the capabilities of electric yard tractor technologies in meeting port duty cycle requirements. These demonstration tests will also need to determine overall integration into operations, including battery charging/fueling requirements. The advanced lithium-ion battery Balqon yard tractor is undergoing preliminary testing and will be delivered for testing in container terminal operations by 3rd quarter 2011. The prototype Vision Motors zero emission yard tractor is also anticipated to be delivered for testing by 3rd quarter 2011. Both units will immediately begin an 18-month demonstration period in accordance with an approved Demonstration and Test Plan. The goal is to have zero emission yard tractors fully developed, tested, and commercially available within the next 2 -3 years.

  The top priority is to bring electric yard tractor technologies successfully through the development and demonstration phase, including operational integration, resulting in the commercial availability of zero emission yard tractors in the near term.

  Advanced yard tractor technologies, such as diesel hybrid electric, have also been successfully demonstrated under the TAP. These technologies have the potential to achieve near-term emission reductions from diesel-fueled yard tractors and can serve as bridge technologies until electric yard tractors are fully commercialized.

  Because battery electric yard tractors are anticipated to carry a cost premium compared to conventional diesel yard tractors, the availability of financial incentives to buy down a portion of the incremental capital cost of the electric technology may be necessary in the near term. Dedicated electric yard tractor recharging infrastructure may also be required and will add additional cost. Costs for equipment maintenance however are expected to be reduced from conventional equipment. To fully or partially offset the incremental cost for zero emission technologies that reduce emissions above and beyond the CARB Cargo Handling Equipment rule, the ports should encourage agencies such as the Department of Energy (DOE), California Energy Commission (CEC), EPA, CARB and AQMD to make financial incentives available.

- Continue to work with terminals operators to select additional zero emission CHE technologies for demonstration through the TAP process, with oversight by the TAC.

- Working with a terminal operator in the Port of Long Beach, the ports commissioned the development of performance specifications for yard tractors. The final specification information, which was completed in 2009, is posted on the ports' CAAP website. The ports continue to work with terminal operators to develop performance specifications for additional equipment types, operational requirements, and integration strategies for zero emission cargo handling equipment.

- Continue to facilitate the electrification of RTGs. Kits that convert diesel generator powered RTG cranes to grid electricity are commercially available. The ports should continue to facilitate implementation of this technology for port terminals, where feasible, through ensuring adequate electrical capacity and infrastructure at the terminals. The ports should also encourage the agencies, such as DOE, CEC, EPA, CARB, and AQMD, to make financial incentives available to offset incremental costs. The ports can also apply for grants from government agencies on behalf of port terminal operators as needed.
- Expansion of RMGs into terminal operations, as feasible and appropriate, should also be encouraged. Typically, because RMGs require installation of rail tracks, implementation of RMGs will be more appropriate during new terminal construction or renovation of existing terminals. The ports are currently requiring electric RTGs or RMGs in new or redeveloped terminal projects.
- As needed, the ports can also apply for grant funding assistance on behalf of terminal operators to support zero emission CHE demonstration and deployment at marine and intermodal terminals. Each port has previously provided this type of support to their terminal operators for equipment retrofit, replacement and repower projects by applying to grant programs that are only available to government entities.

In the longer term, the ports could also:

- Continue to move forward with TAP demonstrations of advanced zero emission technologies for all CHE, including broader operational and durability testing. The ports should pursue the demonstration of electric technology applied to other types of CHE, specifically container top-handlers that comprise 9% of the ports' CHE equipment inventory but account for 22% of total CHE DPM emissions and 27% of total CHE NOx emissions;
- Continue to facilitate electrification of RTGs and RMGs, and work with marine and intermodal terminals to identify additional opportunities for integrating and implementing zero emission terminal operations;
- Promote ongoing improvements in battery technologies through the TAP;
- Assess the need for battery charging or hydrogen fueling station infrastructure with larger-scale zero emission CHE deployment, and assist as needed and appropriate;
- Assist with identifying funding support for purchases of zero emission equipment and/or terminal electrification, which may include applying for grants on behalf of terminal operators.

3.7. Zero Emission Options for Regional Rail Locomotives

The ports understand that locomotive emissions impact communities near the port complex and along goods movement rail corridors within the SoCAB. Thus, there is a compelling need to address locomotive emissions both at the in-port and regional levels. While the challenges presented in adapting zero emission technologies to rail locomotive operations are considerable, they are by no means insurmountable.

The ports, in partnership with rail stakeholders from both government and industry, must develop a recommended course of action to substantially reduce emissions from rail locomotives at both the in-port and regional levels. It is essential that any zero emission rail concept identified for possible implementation be developed and demonstrated with the cooperation and concurrence of several key stakeholders, particularly the U.S Department of Transportation Federal Railroad Administration (FRA) and the Class 1 railroads that serve the ports, BNSF Railway and UP Railroad. Further, it must be understood that due to the complexities associated with zero emission rail technologies, the timeframe for zero emission integration with rail operations is substantially longer compared to technology options for other sources discussed in this report. Therefore, the ports must continue to pursue the CAAP strategies in the interim for reducing rail emissions, even as they work to identify viable and feasible zero emissions options for the long term that could be integrated into railroad operations.

The application of zero emission technologies to rail locomotive operations within and beyond port boundaries is a far more complex task than for short-haul drayage and CHE. First, the technical and programmatic assessments conducted by the ports relative to port-related rail operations revealed that implementation challenges will exist related to right of way entitlements and future track capacity to accommodate optimized or high frequency container moves by rail between marine terminals and near-dock intermodal facilities. Second, the ports' authority as it pertains to rail operations is limited, specifically on the Alameda Corridor and particularly beyond port boundaries. However, despite these challenges, the long-term implementation of zero emission technologies for rail operations must be pursued in cooperation with all stakeholders to address in-port and regional locomotive emissions.

3.7.1 An Overview of Rail Operations at the San Pedro Bay Ports

Port rail emissions represent 5% of the combined ports' total emissions inventory for DPM and 8% of the NOx emissions. Port efforts to further reduce port-related rail emissions remain a main concern. In fact, the effort to utilize best available control technologies to mitigate locomotive emissions is a priority of the ports' TAP.

Railroad operations at the ports are typically described in terms of two different types of operation, line-haul and switching. Line-haul refers to the movement of cargo over long distances (e.g., cross-country) and occurs within the port as the initiation or termination of a line-haul trip, as cargo is either picked up for transport to destinations across the country or is dropped off for shipment overseas. Switching refers to short movements of rail cars, such as in the assembling and disassembling of trains at various locations in and around the ports, sorting of cars of inbound cargo trains for subsequent delivery to marine terminals, and short distance hauling of rail cargo within the port complex.

The ports are served by three rail companies:

- BNSF Railway
- UP Railroad
- Pacific Harbor Line (PHL)

BNSF and UP are designated Class 1 railroads[11] and operate both within and outside of the port boundaries. Both operate national fleets under the regulations and scrutiny imposed by the FRA. PHL is the switcher locomotive operator within the port boundaries, controlled under operating agreements with both ports. Locomotives used for line-haul operations are typically equipped with large, powerful engines of 4,000 horsepower (hp) or more, with each railroad operating a variety of different locomotive models. Switcher locomotives are smaller, typically having one or more engines totaling 1,200 to 3,000 hp.

3.7.2 Ongoing Efforts to Reduce Locomotive Emissions

The 2010 CAAP Update includes measures targeting continued reductions in locomotive emissions. Specifically, CAAP Measure RL3 ("New and Redeveloped Near-Dock Rail Yards") outlines the strategy to achieve significant reductions in locomotive emissions through the accelerated turnover of the existing locomotive fleet, replacing existing locomotives with newer, lower emitting models. The goal of this measure is to have the Class 1 railroads incorporate the cleanest locomotive, CHE, and HDV technologies into near-dock operations. Measure RL3 establishes the goal that the Class 1 locomotive fleet associated with new and redeveloped near-dock rail yards meets a minimum performance requirement of an emissions equivalent of at least 50% Tier 4 line-haul locomotives and 40% Tier 3 line-haul locomotives when operating at the port properties by 2023, to support CARB's published goal of 95% Tier 4 line-haul locomotives serving the ports by 2020. In addition, RL3 will implement idling restrictions, the use of cleaner fuels and evaluation of cleaner locomotive technologies.

[11] The Surface Transportation Board defines a Class I railroad in the United States as "having annual carrier operating revenues of $250 million or more" after adjusting for inflation using a Railroad Freight Price Index developed by the Bureau of Labor Statistics.

Additionally, the ports amended PHL's operating agreements in 2006 to provide funding assistance for the replacement of PHL's existing locomotives with new locomotives meeting Tier 2 emission standards. The locomotives purchased under the amended agreements were delivered during 2007 and 2008; and immediately thereafter, PHL retired the last of the pre-Tier 2 locomotives. Since 2009, PHL's fleet has consisted of 16 Tier 2 locomotives and six "multi-engine genset switcher" locomotives that are powered by three relatively small diesel engines rather than one large engine. These multi-engine genset switcher locomotives use Tier 3 engine technologies. Further, under subsequent amendments to the operating agreements in 2010, PHL is now moving forward with repowering the 16 Tier 2 locomotives with engines that meet even cleaner Tier 3 + standards prior to the end of 2011.

Finally, the ports and UP are participating in an emerging technology demonstration of a Johnson Matthey diesel particulate filter retrofit device for locomotives, anticipated to reduce DPM emissions by over 85%. The project is being funded by a combination of a grant from CARB secured by the ports and TAP funding.

3.7.3 Jurisdictional Authority

The vast majority of line-haul trains bound for destinations outside the port utilize the Alameda Corridor, a 20-mile dedicated rail line running between the San Pedro Bay area and downtown Los Angeles. The ports' ability to impose zero emission requirements on Class 1 locomotives that use the Corridor is substantially limited by the 1988 Alameda Corridor Use and Operating Agreement between the Cities of Los Angeles and Long Beach, ACTA, BNSF and UP.

Beyond the Alameda Corridor Use and Operating Agreement, the ports also have long-term agreements with BNSF and UP that guide track use. These "Use of Tracks" agreements contain long-term conditions that cannot be changed via lease or tariff.

Further, Class 1 locomotives and rail transportation are regulated on a federal level by the EPA, FRA and STB. The EPA adopts emission standards for new and re-manufactured locomotive engines and approves state implementation plans under the Clean Air Act. CARB has entered into voluntary Memorandums of Understanding (MOUs) with the Class 1 railroads to achieve emission and health risk reductions through accelerated turnover of older locomotives with newer, cleaner locomotives and through measures to reduce impacts from railyard operations.

Given the existing agreements and jurisdictional limitations, development and demonstration of zero emission technologies and measures to implement these technologies are most effectively accomplished through a cooperative partnership with the railroads and participating railroad authorities.

3.7.4 Status of Zero Emission Technologies Applicable to Rail Locomotives

As discussed in Section 1, 94% of DPM emissions and 93% of NOx emissions associated with port-related rail operations in 2009 were generated by line haul locomotives. Port-related locomotive emissions are a regional source of air pollution; thus, zero emission options targeting locomotive emissions should be primarily pursued on a regional scale, with the prospect that these options may potentially be applicable to in-port operations.

All zero emission options identified for regional rail use electricity. Rail electrification options that may need to be explored include, but are not limited to:

- Incorporation of LSM technologies into existing rail beds;
- OCS to power electric or dual-mode locomotives; and
- Battery electric tender car.

There are significant operational issues that must be addressed when contemplating the use of rail-related zero emission technologies on a regional scale within the SoCAB, specifically availability of electrification infrastructure and use of dedicated electric-powered locomotives. For example, it must be determined how a dedicated electric-powered locomotive will continue to operate beyond the end of the SoCAB's geographic boundary, if its power source does not continue beyond the SoCAB. The railroads have expressed concerns about any zero emission option that requires a change out of locomotives upon entering or leaving the SoCAB. This presents a serious operational constraint to advancing dedicated electric-powered locomotives as a viable option.

When considering these operational constraints, LSM technology has several potential advantages that warrant further consideration:

- LSM can be adapted to existing rail beds, but does not require electrification of the rails themselves. This propulsion system consists of concrete-encased motor winding modules mounted between rails that provide a magnetic field. Permanent magnets are attached to the bottom of a standard rail car carrying a fully loaded single or double-stacked container. This all-electric approach is free of any exposed high-voltage third rails or OCS wires. Power is provided only to the area of track around each vehicle by using solid-state electronic switches. There is no conflict with conventional diesel locomotives using tracks retrofitted with LSM.
- Conventional rail cars can be used on LSM-equipped track with minimum modifications. A standard rail car is equipped with two wheel "bogies" (the truck that secures the steel wheels and suspension components). Each rail car bogie is modified with the installation of a magnet

module containing arrays of permanent magnets. These magnet arrays interact with the magnetic field induced in the LSM motor modules and provide the thrust to move and stop the rail car. The system as conceived will be capable of propelling very large loads, including multiple double-stacked railcars. The width of the LSM modules and the length of the magnet arrays will be based on the specifics of the application, but hold the potential to propel complete trains. No modifications are required on the locomotives themselves.

- LSM can be integrated into existing rail beds incrementally. On LSM-equipped track, the locomotive can operate in a zero emission mode; then at the end of the LSM line, the diesel locomotive engine can be started and continue in a conventional operations mode;

- LSM is an option that is ready for prototype development and demonstration. A demonstration will provide valuable data to better understand how LSM could apply to regional, and potentially in-port, rail operations.

There are some challenges with LSM however that must also be addressed during any evaluation, especially if the technology will be considered for application between the port terminals and the near-dock rail yards. For example, incorporating automation, or self-propelled rail cars, into an LSM option is currently prohibited by the United States Department of Transportation and the FRA, and no LSM technology has been safety certified by the FRA. Further, the existing rail system within the port complex may not have sufficient capacity to accommodate optimized container routing in either an automated or crewed operation mode. Detailed rail simulation and on-dock railyard capacity analysis, based upon current rail planning, indicated that by 2020, there will be insufficient capacity to handle additional LSM rail car moves to and from near-dock railyards beyond normal movement on on-dock trains and other switching movements. Therefore, a thorough understanding of these issues, and the opportunities to overcome them, is an important aspect of the LSM evaluation.

It is also important to note that consistent with the zero emission technology "process approach" and a commitment to preserve flexibility to allow for integration of future advancements, in addition to LSM, other zero emission rail options will continue to be actively identified, evaluated and demonstrated. The TAP will be utilized for this purpose.

3.7.5 Recommendations for Rail Locomotives

The ports' technical and programmatic screening assessment of zero emission technologies for existing rail operations did not identify any solutions that can reasonably be implemented within the near-term (three years). Thus, implementation of CAAP Measure RL3 discussed in Section 3.7.2 is the recommended primary near-term option to address rail locomotive emissions. *Therefore, for near-term in-port and near-dock rail emission reductions, the ports should continue efforts to reduce switch and line-haul locomotive DPM and NOx emissions through implementation of CAAP Measure RL3.*

Both BNSF Railway and UP Railroad have proposed projects forthcoming that will require new or re-negotiated leases. The ports have adopted policies that their leases shall be compliant with the CAAP, and the Boards of Harbor Commissioners have discretion at the time of lease approval to include among the negotiated lease conditions, CAAP Measure RL3 as a lease condition. The Boards have discretion to include other lease conditions, such as a provision that the Class 1 railroads work with the ports to jointly advance zero emission technology demonstrations, and evaluate new feasible technologies for implementation e.g. every seven years (lease reopener). Concurrent with technology demonstrations, collaboration with the railroads and other regional transportation stakeholders should be initiated to identify and better define issues and challenges to implementing zero emission technologies along regional rail corridors from in-port to the edge of the SoCAB.

As regards rail-related zero emission technologies, there is considerable interest to assess the technical feasibility and programmatic viability of applying LSM technology to existing rail infrastructure. AQMD is currently developing a proposal with General Atomics (GA) for demonstration of LSM technology on conventional rail tracks with a single rail car at GA's test facility located in San Diego. The proposed Phase 1 demonstration, or Proof of Concept, is expected to be initiated by 4th Quarter 2011 and would be conducted over an 18-month period. Other partners in this demonstration project could include the Lawrence Livermore National Laboratory and the Center for Commercial Deployment of Transportation Technologies (CCDoTT).

It is envisioned that this first phase Proof of Concept demonstration would be followed by a second phase, 18-month demonstration, with multiple railcars at a rail research and development testing site that can provide FRA certification. The FRA and American Association of Railroads jointly sponsored Transportation Technology Center (TTC) in Pueblo, Colorado offers such a testing site and the Ports, AQMD, and CCDOTT have had exploratory discussions with TTC. To provide technical input and consistency, TTC may participate as a technical observer/advisor in the Phase 1 test at the GA facility.

Staff recommends that discussions continue with all involved parties regarding a near term Proof of Concept demonstration of LSM technology at an offsite test facility. As the proposed demonstration project matures, a staff recommendation for participating in the project as a stakeholder will be brought forward to each port's Board of Harbor Commissioners for consideration, which may include financial participation. It is anticipated that this recommendation will be brought forward to the Boards within the next few months.

Further, if the Phase 1 testing proves that the LSM technology is promising, the ports could participate in the Phase 2 demonstration of the LSM technology applied to multiple rail cars, as appropriate.

The ports should also collaborate with the rail companies and other stakeholders to further evaluate additional zero emission rail technologies, including LSM, OCS, and a battery electric tender car.

In the longer term, beyond three years, the ports should continue to participate, with a stakeholder collaborative, in existing or proposed zero emission rail demonstration projects, as appropriate; continue to collaborate with rail companies and other stakeholders to evaluate strategies for integrating and implementing zero emission technologies into port-related rail operations on a voluntary basis; and work with stakeholders at the local, state and federal levels to secure funding for zero emission rail technologies.

4. Conclusions and Recommendations

As emphasized throughout this report, there is no single off-the-shelf technology or stand-alone strategy to achieve zero emissions at the ports. Instead, attaining zero emission port-related operations will require multiple pathways of action, strong collaborations and regional partnerships, and support – technical, operational and financial – to advance technological innovation and evolution. It is also a dynamic and ongoing process, a framework approach to transition to zero emissions starting with options that can be supported today.

The roadmap defined in this paper is ambitious. It requires near-term commitments and longer term actions from a broad cross-section of stakeholders. Most of all, this roadmap requires flexibility to accommodate new technologies and approaches alongside a commitment to the end goal – achieving the San Pedro Bay Standards – while addressing and overcoming the myriad challenges identified in this report. If successful, however, this roadmap has the potential to dramatically improve air quality for local communities and throughout the region.

The recommendations proposed here – targeting short- and medium-haul drayage trucks, cargo-handling equipment, and rail – adhere to the key principles identified in Section 1.

Recommended near-term and longer term actions are summarized in Table 7.

Table 7: Recommendations for Zero Emission Technology Implementation

Timeline	Source Category	Actions
Near Term **(within 3 years)**	On-Road Drayage	Conduct Technology Advancement Program (TAP) demonstrations of Vision Motors hybrid electric/hydrogen fuel cell and Balqon lithium-ion battery zero emission drayage truck technologies in short-haul port-related operations following approved testing protocols and within specified timelines. Both manufacturers will deliver trucks for testing by 3rd Quarter 2011. Industry representatives will participate in these demonstrations in an advisory capacity, along with the TAP Technical Advisory Committee (TAC), which includes the ports, Environmental Protection Agency (EPA), California Air Resources Board (CARB) and South Coast Air Quality Management District (AQMD); Select additional zero emission truck technologies for demonstration through the TAP process, with input from industry and the TAP TAC; Seek grant funding assistance and industry partnerships to support zero emission truck demonstration and deployment, as needed; Establish regional partnership with the Los Angeles Metropolitan Transportation Authority, Southern California Association of Governments, Gateway Cities, South Coast Air Quality Management District (AQMD), and others. Work together to define regional zero emission freight transport needs and develop criteria for evaluating options for moving forward with zero emission truck technologies on a regional scale; Working with the regional partnership, identify and evaluate specific range extension options for zero emission truck technologies, including hybridization, in-road LSM, and overhead catenary; Work with the regional collaborative to identify potential funding sources.

Timeline	Source Category	Actions
Near Term (within 3 years)	Cargo Handling Equipment	Conduct TAP demonstrations of Vision Motors hybrid electric/hydrogen fuel cell and Balqon lithium-ion battery zero emission yard tractor technologies in port-related operations following approved testing protocols and within specified timelines. Both manufacturers will deliver yard tractors for testing by 3rd Quarter 2011; Working with terminal operators, select additional zero emission cargo handling equipment technologies for demonstration through the TAP process, with TAC oversight; Working with terminal operators, develop performance specifications, operational requirements, and integration strategies for zero emission cargo handling equipment; Continue to facilitate electrification of RTGs and RMGs by ensuring adequate electrical capacity is available at marine terminals and require their use in new and redeveloped terminal projects; Apply for grant funding assistance to support zero emission cargo handling equipment demonstration and deployment at marine terminals, as needed.
	Rail Locomotives	Participate (with AQMD, the Center for Commercial Deployment of Transportation Technologies, and other stakeholders) in a proposed Proof of Concept demonstration of LSM technology applied to a single rail car test at the General Atomics facility in San Diego. The project is anticipated to be initiated by 4th Quarter 2011; Collaborate with rail companies and other stakeholders to further evaluate zero emission rail technologies, including LSM, overhead catenary, and battery electric tender car; As appropriate, participate in a Phase 2 demonstration of LSM technology applied to multiple rail cars. The phase 2 test would be conducted at a testing center equipped to provide Federal Railroad Administration certification, such as the Transportation Technology Center rail test site in Pueblo, Colorado.

Timeline	Source Category	Actions
Longer Term (>3 years)	On-Road Drayage	Conduct broader operational and durability demonstration testing of advanced zero emission drayage truck technologies in short-haul port-related operations, as needed; Working with industry, evaluate operational compatibility of larger-scale zero emission truck deployment; Work with regional partnership on regional zero emission freight strategy implementation, and on demonstration projects for transitional technologies and technologies to extend zero emission truck range, including hybridization, in-road LSM, and overhead catenary; Assist with zero emission truck deployment by identifying funding opportunities and assisting with charging, wayside power or hydrogen fueling infrastructure as appropriate; Promote on-going improvements in battery technologies through TAP.
	Cargo Handling Equipment	Conduct broader operational and durability demonstration testing of advanced zero emission technologies for all cargo handling equipment, as needed; Assist with zero emission equipment deployment by identifying funding opportunities and assisting with charging or hydrogen fueling infrastructure as appropriate; Promote on-going improvements in battery technologies through TAP; Continue to facilitate electrification of RTGs and RMGs, and work with marine terminals to identify additional opportunities for integrating and implementing zero emission terminal operations.
	Rail Locomotives	Continue to participate, with a stakeholder collaborative, in existing or proposed zero emission rail demonstration projects, as appropriate; Continue to collaborate with rail companies and other stakeholders to evaluate strategies for integrating and implementing zero emission technologies into port-related rail operations; Work with stakeholders to secure funding for zero emission rail technologies.

long beach unified school district

RESOLUTION NO. 011712-A

A RESOLUTION OF THE GOVERNING BOARD OF EDUCATION OF THE LONG BEACH UNIFIED SCHOOL DISTRICT OPPOSING CERTIFICATION OF THE SOUTHERN CALIFORNIA INTERNATIONAL GATEWAY FACILITY ENVIRONMENTAL IMPACT REPORT AS CURRENTLY CIRCULATED BY THE PORT OF LOS ANGELES

WHEREAS, the Port of Los Angeles has prepared a Draft Environmental Impact Report (EIR) (September 2011) for the Southern California International Gateway (SCIG) Project which proposes the development of 153 acres of new and substantially expanded intermodal railyard operations that would transfer containerized cargo between trucks and railcars; and

WHEREAS, in accordance with the California Environmental Quality Act, the District has the right to evaluate and comment on the EIR; and

WHEREAS, the SCIG Project is in a location close to sensitive receptors that will adversely affect the District's students and staff as nearby schools include Webster Elementary, Garfield Elementary School, Muir Elementary School, Stephens Middle School, Hudson K-8 School, Cabrillo High School, Reid High School, and Bethune Transitional School; and

WHEREAS, the SCIG Project EIR fails to adequately disclose significant project impacts, including impacts to District schools, staff, and students, because the EIR analysis is predicated upon illusory baseline conditions that mislead the public as to the reality of the impacts, and the EIR does not use established cancer risk factors that account for the greater sensitivity of students to toxic air contaminants; and

WHEREAS, the SCIG Project EIR does not adequately address or mitigate noise, traffic, air quality, and human health risk impacts to schools and other sensitive receptors, fails to adequately evaluate reasonable alternatives to the proposed Project, and fails to provide sufficient evidence that the zero emissions alternative is infeasible; and

WHEREAS, the SCIG Project EIR fails to adequately and accurately assess the cumulative impacts of the SCIG project in connection with other substantial development projects that will generate cumulative emissions that affect the District's schools, students and staff; and

WHEREAS, it is critical to the District as a policy matter to be sure that the emissions and other impacts of development projects on the District's schools, students, and staff are fully disclosed and mitigated, and

WHEREAS, the inadequacies of the EIR prevent the District from evaluating the true environmental consequences of the SCIG Project upon nearby school facilities and making a determination on whether to support or oppose the project.

NOW, THEREFORE, THE BOARD OF EDUCATION OF THE LONG BEACH UNIFIED SCHOOL DISTRICT DOES HEREBY RESOLVE, DETERMINE AND ORDER AS FOLLOWS:

Section 1. That the Board does hereby find and determine that the foregoing recitals and determinations are true and correct.

Section 2. That the Board of the District hereby formally opposes certification of the SCIG project EIR in its current form, and requests recirculation after completion of substantial revisions to ensure it adequately evaluates the environmental impacts on District students, staff and facilities.

ADOPTED, SIGNED AND APPROVED, this **17th day of January, 2012.**

BOARD OF EDUCATION OF THE LONG BEACH UNIFIED SCHOOL DISTRICT OF LOS ANGELES COUNTY, CALIFORNIA

Subject: Comments on Southern California International Gateway Project (Notice of Preparation)

Dear Dr. Appy:

The Long Beach Unified School District ("District") appreciates the opportunity to comment on the Notice of Preparation ("NOP") prepared for the proposed Southern California International Gateway Project ("Project") by the Port of Los Angeles/City of Los Angeles Harbor Department ("Port"). As the Port may be aware, the District is statutorily required to provide safe and clean school facilities and to provide a high quality public education to students within its boundaries. While the District was originally established in 1885 with fewer than a dozen students meeting in a borrowed tent, the District is now fully responsible for providing school facilities and public education services to more than 95,000 students in 95 public schools in the cities of Long Beach, Lakewood, Signal Hill, and Avalon on Catalina Island. It is the third largest school district in the state of California and employs more than 8,000 teachers and staff, making it the largest employer in the City of Long Beach.

In addition to establishing high standards of academic excellence for its students, the District is committed to providing a safe environment and school facilities for its students and employees. Thus, the District's primary concern in its review of the NOP is to distinguish the environmental impacts which must be properly addressed, analyzed, and mitigated to assure an environment conducive to learning. This letter, therefore, identifies Project impacts which may effect the health, safety and welfare of the students and staff of schools located closest to the proposed Project facilities. The Project EIR must address all possible future impacts on the District, including the District's ability to develop new school facilities and/or expand existing schools in accordance with state mandated requirements.

Overview of Potential Project Impacts on School Facilities

The proposed Project described in the NOP is generally bounded by the Terminal Island Freeway to the east, Sepulveda Boulevard to the north, the Dominguez Channel to the west, and Pacific Coast Highway to the south and portions of the Project would be located in the Cities of Los Angeles, Carson, and Long Beach. The proposed Project consists of a near-dock rail loading and unloading facility to facilitate the movement of container freight in and out of the Port by rail. The District understands that completion of the proposed Project will allow the Port to accommodate the increased rail and truck traffic associated with the existing and future levels of containerized freight the Port plans on handling.

Based on the District's review of the NOP and the Project area, the District believes that there are at least seven schools, a Child Development Center and a maintenance facility currently operating in the vicinity of the Project site and/or planned Project facilities/operations. These school facilities are listed below and are all within less than one mile of the Project or portions thereof, with the closest school located only 210-feet away (see attached Figure 1):

1. Webster Elementary School – 1755 W. 32nd Way
2. Stephens Middle School – 1830 W. Columbus Street
3. Cabrillo High School – 2001 Santa Fe Avenue
4. Hudson Middle School (& Maintenance Facility) – 2335 Webster Avenue
5. Reid High School – 2152 W. Hill Street
6. Garfield Elementary School – 2240 Baltic Avenue
7. Muir Elementary School – 3038 Delta Avenue
8. Bethune Transitional Center (school for homeless students) – 2041 San Gabriel Avenue
9. Child Development Center – 2209 Seabright Avenue

Given the proximity of the Project to the above described schools, the District is very concerned that Project implementation could have a number of potentially significant direct and indirect impacts on the District's school facilities identified above, as well as the students and staff using these facilities. The District will provide its specific concerns in greater detail below, but the District is particularly concerned that the EIR analyze, address, and mitigate any potentially significant impacts associated with the following:

1. Hazardous air emissions associated with the rail yard, increased rail operations, and additional truck traffic from the Project.

2. Noise associated with the rail yard, increased rail operations, and additional truck traffic from the Project.

3. Public health and safety issues associated with spills, leaks, or other accidents from rail or truck traffic as well as any pipelines within the vicinity of District facilities.

4. Traffic impacts associated with additional truck traffic to and from the Project site generating health and safety issues, such as additional air pollution and increased traffic on routes to and from school sites that students may utilize.

Potential Mitigation Measures

In order to ensure none of the above described Project impacts rise to a potentially significant level, the District suggests the EIR analyze the following potential mitigation measures to offset such impacts:

1. Construction of gymnasiums/multipurpose rooms at schools currently without such facilities so that District students and staff have indoor facilities for exercise and other activities to avoid hazardous emissions or unhealthful air quality.

2. Construction of enclosed lunchroom facilities so that District students and staff have indoor facilities for lunch and other activities to avoid hazardous emissions or unhealthful air quality.

3. Improvements to District air conditioning/filtration units at schools, which do not currently have sufficiently modern or appropriate equipment necessary to ensure adequate indoor air quality.

4. Construction of sound barriers/installation of dual-paned windows to offset noise impacts to potentially impacted schools.

5. Construction or improvement of rail and/or traffic signals and crossings to ensure the safety of students en route to school facilities given the potential increased traffic associated with the Project.

Specific Concerns

In the paragraphs that follow, the District describes the specific concerns it has concerning the Project's potential environmental, health and safety impacts and requests that the Port thoroughly address these issues in the upcoming EIR. The EIR should fully recognize that schools must be treated as a sensitive land use given the concentration of young children within and around these facilities for many hours of the school day and during after-school activities. In addition, students themselves must be treated as sensitive receptors given the disproportionate impacts certain pollutants have on children.

Secondly, the District requests that the EIR recognize the unique nature of school facilities under California law. Schools are one of the most protected and heavily regulated land uses. The development of new schools and expansion and modernization of existing schools trigger a myriad of special regulatory requirements for the District that are enforced by a variety of state agencies, which makes finding an adequate school site, and/or expanding an existing school site challenging. These regulations include review and approval by the California Department of Education, the Department of Toxic Substances Control and various other agencies, and often trigger special studies to confirm that stringent health and safety standards are met. Such studies may involve various agency consultations and oversight and the use of rigorous study protocols. This very high level of review creates great difficulty in constructing school facilities. Therefore, the District is very concerned that the proposed Project may subsequently preclude it from upgrading or expanding the schools in the vicinity of the Project described above. These statutorily proscribed site constraints may also make it impossible to find new or replacement school sites in this community after the Project is complete.

Title 5 and Statutory School Siting Issues

The District requests that the EIR evaluate the Project's potential direct and indirect impacts on nearby school facilities in conformance with the school siting requirements established in Title 5, California Code of Regulations (CCR), the Education Code, and the Public Resources Code. If the Project, or any portion thereof, involves the activities described below, the EIR must contain the appropriate study including a level of analysis sufficient to satisfy the state agencies with regulatory authority over the District. To accomplish this level of analysis, the District recommends that the Port analyze Project impacts on District facilities and students as though it were the District. In other words, if a rail line is proposed to be sited within 1,500 feet of school site, the Port should conduct a comparable safety study to that which would be required of the District if it proposed placing a school site within 1,500 feet of the same rail line. Please ensure that the EIR evaluates not only the relationship and proximity of the main components of the Project to the District's school facilities, but also any infrastructure or utilities that would extend to the Project site (especially power lines and pipelines) or other support facilities.

For the Port's reference, Section 14010 of Title 5, CCR contains the following special criteria for potential hazards in the vicinity of school sites:

a. The property line of a school site even if it is a joint use agreement shall be at least the following distance from the edge of respective power line easements: (1) 100 feet for 50-133 kV line; (2) 150 feet for 220-230 kV line; and (3) 350 feet for 500-550 kV line.

b. If the proposed site is within 1,500 feet of a railroad track easement, a safety study shall be done by a competent professional trained in assessing cargo manifests, frequency, speed, and schedule of railroad traffic, grade, curves, type and condition of track need for sound or safety barriers, need for pedestrian and vehicle safeguards at railroad crossings, presence of high pressure gas lines near the tracks that could rupture in the event of a derailment, preparation of an evacuation plan. In addition to the analysis, possible and reasonable mitigation measures must be identified.

c. The site shall not be adjacent to a road or freeway that any site-related traffic and sound level studies have determined will have safety problems or sound levels, which adversely affect the educational program.

d. Pursuant to Education Code sections 17212 and 17212.5, the site shall not contain an active earthquake fault or fault trace.

e. Pursuant to Education Code sections 17212 and 17212.5, the site is not within an area of flood or dam flood inundation unless the cost of mitigating the flood or inundation impact is reasonable.

f. The site shall not be located near an above-ground water or fuel storage tank or within 1500 feet of the easement of an above ground or underground pipeline that can pose a safety hazard as determined by a risk analysis study conducted by a competent professional, which may include certification from a local public utility commission

g. The site is not subject to moderate to high liquefaction or landslides.

h. The shape of the site shall have a proportionate length to width ratio to accommodate the building layout, parking and playfields that can be safely supervised and does not exceed the allowed passing time to classes for the district.

i. The site shall be easily accessible from arterial roads and shall allow minimum peripheral visibility from the planned driveways in accordance with the Sight Distance Standards established in the "Highway Design Manual," Table 201.1, published by the Department of Transportation, July 1, 1990 edition, and incorporated into this section by reference.

j. The site shall not be on major arterial streets with a heavy traffic pattern as determined by site-related traffic studies including those that require student crossings unless mitigation of traffic hazards and a plan for the safe arrival and departure of students appropriate to the grade level has been provided.

k. Existing or proposed zoning of the surrounding properties shall be compatible with schools in that it would not pose a potential health or safety risk to students or staff in accordance with Education Code Section 17213 and Government Code Section 65402 and available studies of traffic surrounding the site.

l. The site shall be located within the proposed attendance area to encourage student walking and avoid extensive bussing unless bussing is used to promote ethnic diversity.

m. The site shall be selected to promote joint use of parks, libraries, museums and other public services, the acreage of which may be included as part of the recommended acreage as stated in subsection (a) of this section.

n. The site shall be conveniently located for public services including but not limited to fire protection, police protection, public transit and trash disposal whenever feasible.

o. The district shall consider environmental factors of light, wind, noise, aesthetics, and air pollution in its site selection process.

p. Easements on or adjacent to the site shall not restrict access or building placement.

q. If the proposed site is on or within 2,000 feet of a significant disposal of hazardous waste, the school district shall contact the Department of Toxic Substances Control for a determination of whether the property should be considered a Hazardous Waste Property or Border Zone Property.

The District also requests the Port and the EIR consider and include appropriate analysis of the rail operations issues described in Education Code Sections 17212.2 and the hazardous materials requirements of Public Resources Code Section 21151.4 and 21151.8.

Hazardous Air Emissions

1. The Initial Study indicates that the proposed Project would divert truck traffic using nearby local freeways (e.g., 710 Freeway) to a facility in closer proximity to the Port, which would ease traffic conditions on local freeways and reduce air quality impacts. While the proposed Project may achieve a positive overall environmental impact for the region as stated in the Initial Study, the proposed Project would substantially decrease localized air quality for the nearby population, including school population, in the Project area. The proposed Project would place more traffic on local roadways, primarily on Pacific Coast Highway. In addition, the District anticipates that the increased efficiency of the loading and transport freight operations at the Port will lead to additional ship, train, and vehicle trips, thereby increasing the related air pollutant emissions. Therefore, the EIR should identify all hazardous air emission sources and their impacts on the school population, including the proximity of District school facilities to the potential emission sources. Specifically, the EIR should consider the following issues:

1a. The EIR must clarify how any additional vessel traffic resulting from the proposed Project would be mitigated and describe how vessel traffic would be monitored. The Initial Study states that the proposed Project would not result in changes in vessel traffic levels or patterns to create substantial safety risks. However, the District believes that increases in the processing of freight would lead to accepting more freight from additional ships. If it is determined that the proposed Project may lead to additional ships utilizing the port facilities, air pollutant emissions from these additional ships must be accounted for in both the emissions inventory and health risk analysis. The EIR must describe how potentially improved handling of containerized cargo would improve vessel traffic flow and identify how it relates to the emissions. (We suggest you review a recent Court of Appeals case on the relationship between infrastructure sizing and its impact on growth. *See Laub v. Davis*, 2005 DJDAR 12079 (October 7, 2005)).

1b. The EIR should include a health risk analysis that considers the potential health impacts from both the exterior and interior exposure of students to train related emissions in combination with existing port emissions. The proposed Project would involve an increase in the use of trains along the Union Pacific Railroad (UPRR) to transport freight as opposed to trucks. In addition, the proposed track extension would locate emission sources closer to the existing schools. Therefore, the healthrisk analysis performed for the Project needs to consider the both the exterior and interior exposure of students.

1c. The EIR must include a health risk analysis that evaluates the potential health risk for all sources that may potentially affect the health of the students within the District including appropriate air dispersion modeling (as described in Education Code Section 17213(c)(2)(C)). The proposed Project has the potential to increase localized concentrations of air pollutants in the vicinity of the Project site. Though Project-related air pollutant concentrations will be evaluated within the technical studies conducted under CEQA, the District is concerned about the cumulative effects of air pollutant concentrations on the health of the students at District schools. The California Air Resources Board's *Diesel Particulate Matter Exposure Assessment Study for the Ports of Los Angeles and Long Beach* states that there are already significant health risks associated with existing port related air pollutant concentrations. The District is concerned that the Project would degrade the air quality conditions at District schools.

1d. The EIR must include a health risk analysis that evaluates potential impacts on indoor air quality at the District's school facilities and whether the use of High Efficiency Particulate Air (HEPA) filter systems at District schools would improve indoor air quality. The District is concerned that air pollutant concentrations may adversely affect the indoor air quality at District schools.

1e. The EIR must include an evaluation of how the potential construction of gymnasiums/multipurpose room with HEPA filter systems could improve the air quality of students and faculty. The provision of gymnasiums/multipurpose room would provide an alternative to exercising outside where air quality is considered poor due to the Port and Port of Long Beach being the largest single source of PM^{10} within the south coast air basin. The provision of gymnasiums/multipurpose room as mitigation measures is essential because children and the elderly represent the most vulnerable segment of our population and children have higher respiratory rates due to their level of physical activity.

1f. The California Air Resources Board (CARB) has published the *Diesel Particulate Matter Exposure Assessment Study for the Ports of Los Angeles and Long Beach.* This Study has identified current operations at the Ports of Long Beach and Los Angeles as major sources of PM10. It also stated "Growth forecasts predict that trade at the POLA and POLB will triple by 2020, resulting in a 60 percent increase in diesel PM emissions from current levels unless further controls are enacted." This increase in emissions and associated health risk due to the increased port activities must also be evaluated within the EIR.

1g. The proposed Project may expose District students and staff to unhealthful air quality conditions. We request that the Draft EIR address these serious concerns and identify specific mitigation measures to reduce all such impacts to less than significant.

Noise and Vibration Impacts

2. The EIR must include noise and vibration evaluation at each of the school sites potentially impacted by the proposed Project. The existing schools currently experience extensive noise from trains (especially along the San Pedro Branch line that extends along the eastern boundary of the Project site) and trucks associated with the existing industrial activities. The increased number of train and vehicle trips would contribute to the increased noise and vibration impacts for the existing schools. The typical approach for the assessment of noise uses a 24-hour CNEL noise metric which averages noise levels from train activity with periods of no train activity over a 24-hour period. This approach would understate the impact of train noise which is most evident during single train passings. The noise impact assessment should evaluate the noise impact from single train events and not be averaged with periods of no train activity. This single event train noise impact assessment needs to include a discussion of how train noise would result in speech interference at 45 dBA Leq. Increasing the frequency of train operations may lead to a greater number of occurrences of interference of speech intelligibility of students and faculty. This increase in noise may restrict the District's ability to expand and improve the existing schools. Noise analysis should identify these sensitive receptors and evaluate site specific impacts and mitigation for each school. The EIR should identify all feasible mitigation measures necessary and appropriate to reduce noise and vibration impacts to any of the District's school facilities potentially impacted by the Project.

3. The noise impact evaluation also needs to consider potential mitigation measures such as a perimeter sound/barrier wall along the Terminal Island freeway at Hudson to protect the site from noise, traffic, and viewing activities at the facility. Other types of mitigation measures that should be considered are removal of at-grade crossings between the railroad and streets, use of quadgate railroad crossing systems, trenches to reduce vibration impacts, construction of gymnasiums to provide a quiet athletic environment and structural acoustic improvements at schools.

Traffic and Transportation:

4. In page 34 of the IS, it is indicated that the proposed Project might result in the increased use and traffic on the existing streets in the Project area, which could increase hazards at pedestrian crossings in the vicinity of the District's schools. These crossings are already very busy and pose potential safety hazards to the District's students. The increased traffic from the Project may create potentially significant impacts because the proposed Project would exacerbate the current situation. Further degradation of the current hazardous condition would constitute a potentially significant impact. The traffic study should identify existing and future hazardous intersections in the Project vicinity and conduct proper analysis.

Public Health & Safety:

5. The EIR should identify any high-pressurized gas or liquid petroleum lines within the Project site and evaluate the risk of rupturing. The District is concerned about the high pressure gas or liquid petroleum pipelines within the railroad easements in the Project vicinity. The District is concerned that the overall increase in rail traffic would also increase the probability of derailment and pipeline rupture.

6. The EIR should identify potential safety risks related to transport/handling of hazardous materials such as potential for spill, release, leak, and explosion in case of derailment or accident. The District anticipates that an increase in rail usage would also increase the quantity and volume of hazardous materials being transported to and from the Project site.

7. The EIR should identify any overhead or underground transmission power lines above 50 kV. The District is concerned with the current and future electric power sources in association with the EMF effect. The EIR should also identify any plans for relocation, construction, and/or any proposed voltage increase for existing transmission lines.

Cumulative Impacts:

8. The EIR must include a cumulative impacts analysis. The District is concerned about the cumulative effects of the air, traffic, noise, and public health and safety issues related to the Project. While these impacts may be less than significant individually, they may be significant cumulatively.

9. Analysis of cumulative projects must include local development as well as general and anticipated growth within the Project area. The District is concerned that the proposed Project would have compounding effects that extend beyond the defined Project and area. The EIR cumulative impact analysis must consider the Project's growth inducing impacts and associated public health and safety issues that are reasonably anticipated as result of the proposed Project and potential future impacts the Project may have on the District's ability to construct additional school facilities and/or expand existing school sites.

General:

10. The EIR should include a figure (or figures) that shows general locations for all major Project construction and improvements including, but not limited to, all new tracks (e.g., tracks for transfer of marine containers & additional BNSF tracks), fueling areas, a truck in/out gate, etc. Please clarify the Area of Less Frequent Train Movements as shown in Figure 2, Project Site Area. It is uncertain what the Area of Less Frequent Train Movements represents; if that is the area where additional rail tracks are being proposed, please label as such.

11. The significance determination and the analysis must be consistent throughout the Initial Study. There are a number of instances where the Project impacts are called Less Than Significant but it is stated that these impacts will be discussed in the EIR. Where an impact analysis cannot be substantiated in the Initial Study, these impacts should be considered Potentially Significant and further discussed in the EIR. For example in Section VII(b), Hazards and Hazardous Materials, the impact was determined to be less than significant because an Emergency Response Plan and Health and Safety Plans would be developed and these plans are expected to remedy any dangers associated with an upset or accidental release of hazardous materials. However, the Initial Study states that the adequacy of these plans and measures will be addressed in the EIR. If adequacy of these plans could not be substantiated, the impact should be considered Potentially Significant and properly evaluated in the EIR.

12. The EIR must evaluate the impacts of displacing the existing owners/lessees as result of the consequential relocation of Cal Cartage. Notwithstanding the fact that the currently proposed location for the Cal Cartage operation would create greater distance between Cal Cartage and the nearby schools, the displaced industries may move closer to the schools or have other impacts. The EIR must identify all direct and indirect impacts of Project implementation, including cumulative impacts of these displacements.

13. The EIR must include an adequate analysis of Project alternatives including, but not limited to potential alternatives to truck and rail traffic routing as it relates to offsetting any potential impacts to the District's school facilities, students or staff.

Thank you for the opportunity to respond to the NOP and we would like to be included on the mailing list for all future notices and documents pertaining to this Project. The District looks forward to reviewing the EIR when it is released for pubic review. The District would also be happy to meet with the Port and its consultants to discuss the impact of the Project on the District's facilities, students and staff and potential mitigation measures to offset such impacts. The District trusts that the Port and the District can resolve all school facility, student and staff health and safety concerns in a collaborative manner. Please send one complete set of the DEIR to me at the above address when it becomes available. If you have any questions or would like to meet to discuss our concerns, please feel free to contact me at (562) 997-7550.

Sincerely,

Carri Matsumoto
Executive Director
Facilities Development and Planning
LONG BEACH UNIFIED SCHOOL DISTRICT

ALAMEDA CORRIDOR FACT SHEET

projects

Completed Projects

- Alameda Corridor
- Pacific Coast Highway Grade Separation
- Anaheim Pump Station
- Colton Crossing Feasibility Study
- Additional Control Points Project
- CP West Thenard Track Connection Phase 1

Future Projects

- West Thenard Track Connection Phase 2
- SR-47 Expressway
- Cerritos Channel Rail Bridge

Fact Sheet | **Time Line** | **Map** | **Consolidation Activity Report**

Project Description / Overview

The Alameda Corridor is a 20-mile-long rail cargo expressway linking the ports of Long Beach and Los Angeles to the transcontinental rail network near downtown Los Angeles. It is a series of bridges, underpasses, overpasses and street improvements that separate freight trains from street traffic and passenger trains, facilitating a more efficient transportation network. The project's centerpiece is the Mid-Corridor Trench, which carries freight trains in an open trench that is 10 miles long, 33 feet deep and 50 feet wide between State Route 91 in Carson and 25th Street in Los Angeles. Construction began in April 1997. Operations began in April 2002.

Project Need

International trade accounts for one of every 15 jobs in the Southern California region, according to the Los Angeles County Economic Development Corporation. The ports of Long Beach and Los Angeles are the two busiest container ports in the country and, together, the fifth busiest port complex in the world. The ports handled more than $200 billion in cargo in 2001. The rail network serving the ports was not sufficient to accommodate rapidly increasing cargo volumes. The Alameda Corridor consolidated four low-speed branch rail lines, eliminating conflicts at more than 200 at-grade crossings, providing a high-speed freight expressway, and minimizing the impact on communities.

Benefits

- More efficient freight rail movements
- Reduce traffic congestion by eliminating at-grade crossings
- Improvements to Alameda Street
- Multiple community beautification projects
- Cut train emissions
- Slash delays at railroad crossings
- Cut noise pollution from trains
- Reduce emissions from idling automobiles and trucks

Funding

The $2.4 billion Alameda Corridor was funded through a unique blend of public and private sources. Revenues from user fees paid by the railroads will be used to retire debts. Railroads initially paid $15.00 for each loaded 20-foot equivalent unit (TEU) container; $4.00 for each empty container, and $8 for other types of loaded rail cars such as tankers and coal carriers. Over a 30-year period, fees will increase between 1.5 percent and 3 percent per year, depending on inflation. Effective January 1, 2009, fees are $19.31, $4.89 and $9.77 respectively.

Community Programs

Through its contractors and various community partnerships, ACTA administered several programs designed to provide local residents and businesses with direct benefits that will long outlive actual construction.

- Construction industry-specific job training for 1,281 local residents, including 637 placed in union apprenticeships.

30% of all labor hours for Mid-Corridor Trench were performed by local residents living in adjacent zip codes

Through aggressive outreach and technical assistance, ACTA helped disadvantaged (primarily small and woman- or minority-owned) businesses compete for and earn contracts worth more than $285 million, meeting the program goal of 22 percent of all contracts.

On-the-job training and education credits for more than 420 young adults (ages 18-23), who performed community beautification work through the Conservation Corps program.

One-on-one technical consulting for 25 local import-export companies and entry-level, international trade-specific job training for 20 local residents through a joint program with the World Trade Center Association Los Angeles-Long Beach.

Key Features

North-End Project Area

Massive Redondo Junction flyover separates cargo trains, passenger trains, street traffic.

Multiple rail and street bridges add capacity, eliminate traffic conflicts.

Improved rail yard connections enhance cargo flow.

Mid-Corridor Trench

Trench stretches 10 miles long, 33 feet deep, 50 feet wide.

Thirty bridges carry street traffic over the trench, reconnect communities.

Alameda Street improvements ease traffic congestion.

South-End Project Area

Henry Ford Avenue Grade Separation, one mile long, adds rail capacity, eliminates conflicts with street traffic.

Terminal Island Freeway ramp improvements enhance traffic flow.

Multiple higher-capacity rail bridges over water channels speed port access.

ACTA BOARD APPROVES EXPANDED MISSION AND MAKES KEY RECOMMENDATIONS TO REDUCE TRAFFIC CONGESTION

FOR IMMEDIATE RELEASE:
December 4, 2003

CONTACT:
John Canalis (562) 435-5551
Maria Melendres (310) 847-4307

LOS ANGELES COUNTY, CALIF. – Directors of the public agency that built the Alameda Corridor agreed to an expanded mission Thursday to develop and support projects that more effectively move cargo to points around Southern California, ease truck congestion, improve air quality and make roads safer.

The Governing Board of the Alameda Corridor Transportation Authority (ACTA) unanimously adopted several recommendations that would improve the flow of cargo from the ports of Los Angeles and Long Beach to the rest of the region. While the Alameda Corridor provides an uninterrupted express railway for cargo for transcontinental rail lines, an improved regional intermodal network is needed to deliver local cargo to the Southland's major freight distribution centers.

"ACTA's extensive expertise and experience in identifying and developing innovative projects are resources that should be brought to bear on developing goods movement solutions on a regional scale," said ACTA Board Chairman and Long Beach Vice Mayor Frank Colonna. "We have the institutional know-how, the government structure and stature to play a major role in solving what is the most vexing problem facing our region and our transportation infrastructure today."

ACTA's governing board, which includes representatives from the cities and ports of Los Angeles and Long Beach, as well as the Metropolitan Transportation Authority, directed the agency to:

- Coordinate with the ports, shippers, wholesalers and retailers to work together on expanding the operating hours of the intermodal distribution system
- Develop a proposal to optimize existing on-dock rail capacity
- Evaluate the viability of a regional shuttle train operation
- Support the development of a new near-dock ICTF
- Continue working with Caltrans to plan the State Route Expressway/Commodore Schuyler Heim Bridge project
- Participate in goods-movement studies with the MTA and other agencies.

The recommendations were made to the ACTA Board by its Ad Hoc Committee on Goods Movement. The committee, formed by ACTA in September to evaluate a potential expanded role, is composed of Colonna, Los Angeles City Councilwoman and ACTA Board Vice Chair Janice Hahn, Los Angeles Port Commissioner Thomas Warren and Long Beach Port Commissioner James C. Hankla.

2-2-2

"We can't wait any longer to reduce truck congestion in the region, and we must look at all of our options," said Hahn, an early proponent of expanding operational hours at the ports.

This method is currently being successfully implemented at other large international port complexes.

ACTA CEO John T. Doherty said, "These proposed projects could significantly improve the region's goods-movement system while reducing truck congestion on local freeways."

Existing surplus capacity of on-dock rail facilities, for example, could be utilized more efficiently to reduce the number of trucks departing port terminals.

In response to the significant growth of new warehouse distribution centers in the Inland Empire, ACTA will evaluate the development of an inter-regional shuttle train system to deliver cargo to these inland distribution centers. A short-haul system would augment Alameda Corridor cargo destined for transcontinental shipment.

In addition, ACTA will support efforts to develop a new near-dock facility where containers can be loaded onto rail that would transport containers via the Alameda Corridor and eliminate those trucks on freeways destined for downtown rail yards. Union Pacific Railroad operates one such facility in the harbor area, and the Burlington Northern Santa Fe Railway is considering a site in the Wilmington area.

ACTA will continue to cooperate with Caltrans on planning efforts to improve State Route 47 (SR47). Preliminary studies indicate that replacing the Commodore Schuyler Heim Bridge and building an elevated connection between the north side of the new bridge and Alameda Street at Pacific Coast Highway would reduce truck traffic on the Long Beach (710) and Harbor (110) freeways, as well as surface streets. The proposed project would improve traffic safety and congestion in the Wilmington area by eliminating five at-grade rail crossings and three traffic signals on SR47.

Opened in April 2002, the Alameda Corridor consolidated train traffic from four branch rail lines into a high-speed freight rail expressway stretching 20 miles between the Ports of Long Beach and Los Angeles and the transcontinental rail yards and railroad mainlines near downtown Los Angeles. It eliminated conflicts at more than 200 street-level railroad crossings, thereby reducing traffic congestion and air pollution.

The project was built on time and on budget by ACTA, a joint powers authority formed by the Cities and Ports of Los Angeles and Long Beach. The seven-member Governing Board is comprised of two representatives from each Port, one from each City, and one from the MTA.
